**Innate Behaviors, Fig. 2** René Descartes (1596–1650). Philosopher, scientist, and mathematician. (Source: Wikimedia Commons. Rene Descartes, Frans Hals, Artist. Public Domain, Wikimedia Commons. [https://en.wikipedia.org/wiki/File:Frans\\_Hals\\_-\\_Portret\\_van\\_Ren%C3%A9\\_Descartes.jpg](https://en.wikipedia.org/wiki/File:Frans_Hals_-_Portret_van_Ren%C3%A9_Descartes.jpg))

*spirits* would then travel up tube-like nerves to the brain where the spirits would be reversed. The same spirits would eventually travel back down the same nerves and manifest as a motor response. Descartes argued that the same mechanism could be used to explain human reflexive behavior (see Fig. 3).

Descartes believed that animals were limited to involuntary, reflexive behavior; only humans exhibited willful, voluntary behaviors believed to have their origins in the mind – a nonphysical entity where consciousness was thought to reside. Via its connection to the pineal gland, the mind sent willful responses to the body using the same neural tubes. In this way, Descartes was able to employ the same mechanical system for humans while maintaining his mind-body, dualistic philosophy of man as being made in the image of God and separate from the animal kingdom.

Following in Descartes' footsteps, a number of physiologists, anatomists, and psychologists

**Innate Behaviors, Fig. 3** The Withdrawal Reflex. *For example, if the fire (A) is close to the foot (B), the small particles of fire, which as you know move very swiftly, are able to move as well the part of the skin which they touch on the foot. In this way, by pulling at the little thread (CC), which you see attached there, they at the same instant open e, which is the entry for the pore (d), which is where this small thread terminates; just as, by pulling one end of a cord, you ring a bell which hangs at the other end.... Now when the entry of the pore, or the little tube, (de), has thus been opened, the animal spirits flow into it from the cavity (F), and through it they are carried partly into the muscles which serve to pull the foot back from the fire, partly into those which serve to turn the eyes and the head to look at it, and partly into those which serve to move the hands forward and to turn the whole body for its defense.* (From Descartes' *Treatise of Man* (1662). Image Source: Wikimedia Commons. The Withdrawal Reflex. Rene Descartes, Artist. Public Domain, Wikimedia Commons. <https://af.m.wikipedia.org/wiki/L%C3%AAer:Descartes-reflex.JPG>)

began to unravel the true nature of the reflex. Table 1 outlines the major discoveries that occurred over the next two centuries.

Over the next century and a half, the reflex would be integrated into the wider understanding of the nervous system. In psychology, Pavlov's notion of the stimulus-response nature of conditional reflexes would dominate the understanding of all behavior for nearly 50 years (For a detailed summary, see Domjan 2015). In the early part of the twentieth century, John B. Watson (one of the leading behaviorists in America) embraced S-R

learning and would promote the idea that emotional behavior responded to conditioning in a manner similar to other conditional responses, like salivation. His study of Little Albert in which a toddler acquired conditioned fear responses through Pavlovian conditioning techniques would go on to become one of the most famous studies in psychology and learning theory (Watson and Raynor 1920). Not until the work of B. F. Skinner (1938) would the view of voluntary behavior (aka instrumental behavior) truly diverge from the original idea that all behavior was reflexive, as put forth by Descartes.

## Other Innate Behaviors

Three other forms of innate behavior classically described in most textbooks on learning and animal behavior are fixed- and modal-action patterns, taxis, and kinesis.

### Fixed and Modal Action Patterns

Fixed and modal action patterns refer to complex behavioral sequences that require more cerebral involvement than simple reflexes. They occur only in certain nonhuman animal species. Like the reflexes, action patterns are hardwired and involuntary and require releaser stimuli, called *sign stimuli*. Unlike reflexes that tend to occur broadly across the taxonomic rank, action patterns are species-specific behaviors. They are usually associated with courtship, reproduction, territoriality, aggression, foraging/caching, and predator evasion. They tend to occur uniformly in a fixed manner, or in modal ways with limited variability across all members of a single species (although they can be restricted to one sex or the other). All fixed and modal action patterns are genetically determined; many appear at sexual maturity and are often linked to hormonal states. Those action patterns associated with territoriality and courtship may appear only during the breeding season. Familiar examples include elaborate courtship displays in many bird species ranging from familiar backyard birds like wrens, robins and doves to more exotic birds like the grebes, sand hill cranes, grouse, and the classic peacock (Fig. 4).

**Innate Behaviors, Table 1** Over two hundred years of research on the reflex after Descartes

| Scientist        | Year (s) | Nationality and field of study | Discovery                                                                                                                          |
|------------------|----------|--------------------------------|------------------------------------------------------------------------------------------------------------------------------------|
| Swammerdam       | 1664     | Danish biologist               | Demonstrated that the reflex was caused by the external “irritation” of the nerve.                                                 |
| Von Leeuwenhoek  | 1717     | Dutch biologist                | Describes nerve fibers in cross section                                                                                            |
| Galvani          | 1791     | Italian biologist              | Discovered that external stimulation using electricity caused movement in dissected frog leg muscles                               |
| Bell & Magendie  | 1811     | English physiologist           | Demonstrated that separate sets of nerves transmitted information from the sense organs to the CNS and from the CNS to the muscles |
| Magendie         | 1821     | French physiologist            | Differentiates dorsal and ventral roots of the spinal column                                                                       |
| Hall             | 1837     | English physiologist           | Discovered that a decerebrate newt moved when the skin was pricked                                                                 |

The classic example of modal action patterns occurs in the three-spined stickleback fish (*Gasterosteus aculeatus*). The tiny fish is found in waters north of 30°N. They are anadromous, living at sea except during the breeding season when they nest in brackish or freshwater. The male stickleback establishes and defends a breeding territory; he will build a tube-like nest in the substrate with sand, algae, and a silk-like substance secreted from the kidneys called *spiggin*. When the nest is complete, the male stickleback then begins to exhibit various aggressive and defensive territorial behaviors and ritualistic courtships behaviors in response to specific sign stimuli (Fig. 5).

During the breeding season (late March to early August), adult sticklebacks migrate into freshwater. As a result of hormonal changes, breeding males' bellies flush red, and they begin to set up territories and build their tube-like nests. Any other breeding male conspecific that enters a resident male's territory is met with the erection of the three spines on the dorsal side of the fish (a reflex), and modal action patterns that include aggressive rushing and biting that will continue until the intruder male leaves the territory.

In a classical study of these aggressive modal action patterns in the stickleback, Tinbergen

employed the use of clay models to determine the nature of the specific releaser, or sign stimulus. He found that almost any shape of clay would suffice to elicit aggressive behavior as long as the ventral side of the clay was painted red (Fig. 6).

Once a male stickleback has successfully repelled conspecific competitors, his reproductive success is the result of elaborate combination of reflexes and model action patterned interactions with the female. The presence of a gravid female into the breeding male's territory elicits modal fanning and swimming in a zigzag direction toward the female and then toward the nest. Once the female approaches the nest, the male will swim through the nest repeatedly until the female enters the nest, or leaves the area. Pressure on her lateral line serves as a releaser stimulus for the reflex of egg-laying. The male will follow her into the nest and fertilize the eggs as she is forced out. The presence of the female serves as the necessary sign stimulus for the initial release of these courtship behaviors in the male (Candolin 1997).

Early in the field of ethology, action patterns were believed to be somewhat fixed and inflexible. Once elicited, the behavior would run its course almost automatically despite potential

**Innate Behaviors, Fig. 5** Juvenile and adult three-spined stickleback fish (*Gasterosteus aculeatus*). The red belly of the breeding male serves as sign stimuli for territorial aggression and courtship. Note: the female in the nest.

(Image Source: Wikimedia Commons. *Gasterosteus aculeatus*, Alexander Francis Lydon, Artist. Public Domain, Wikimedia Commons [https://commons.wikimedia.org/wiki/File:Gasterosteus\\_aculeatus\\_1879.jpg](https://commons.wikimedia.org/wiki/File:Gasterosteus_aculeatus_1879.jpg))

interruptions. Eibesfeldt (1974) described persistent egg-case spinning in banana spiders (*Cuppiennius salei*) despite his attempts to interrupt the behavioral sequence by removing the baseplate of the cocoon, or by removing her silk organ. The female spider failed to make adjustments to the sequence of behaviors to accommodate these interruptions. However, more recently, it has been shown that modal action patterns can be somewhat flexible in some ways. Although

the sequence of behaviors appears to be relatively consistent across individuals, Candolin (2017) showed that the rate and duration of modal courtship behaviors in three-spined stickleback fish diminished in the presence of a predator. As a result, female choice declines and individual reproductive success can be reduced.

Taxis

Taxis is the term for innate locomotor responses to specific environmental/releaser stimuli. Taxes involve directed movement toward (positive taxis) or away (negative taxis) from the specific stimulus. Taxes, like action patterns, may appear willful in that they involve directed movement that is responsive to the environment. However, taxes, like action patterns, are innate and consistent across all members of a species. Taxes are present across a wide variety of species including vertebrates and invertebrates. Table 2 outlines examples of various forms of taxes.

*Synthesis of Action Patterns and Taxes.* Lorenz and Tinbergen (1938) had shown that, in some species, action patterns may evolve into even more elaborate behavioral sequences through the superimposition of orienting motions onto fixed- or modal-action patterns. These orienting motions result from minor shifts or changes in the sign stimulus that elicit accommodating adjustments to the otherwise, stereotyped action pattern.

**Innate Behaviors, Fig. 6** A male three-spined stickleback fish during the breeding season and an example of the clay models used by Tinbergen (1951) to elicit territorial aggression. (Image Source: Stickleback and Clay Model, Open Stax, Creative Commons, [https://cnx.org/contents/GFy\\_h8cu@10.53:mNyatk93@4/Behavioral-Biology-Proximate-and-Ultimate-Causes-of-Behavior](https://cnx.org/contents/GFy_h8cu@10.53:mNyatk93@4/Behavioral-Biology-Proximate-and-Ultimate-Causes-of-Behavior))

**Innate Behaviors, Table 2** Examples of taxes across a variety of species

| Type of Taxes | Releaser stimulus       | Species                       | Description                                                                    |
|---------------|-------------------------|-------------------------------|--------------------------------------------------------------------------------|
| Anemotaxis    | Wind                    | Flying insects like locusts   | Flight corrections using hair sensilla on the head                             |
| Galvanotaxis  | Electrical current      | Electric fishes               | Two-way electrocommunication                                                   |
| Gravitaxis    | Gravity                 | King crab larvae; fruit flies | Moving toward or away from gravitation pull, aka geotaxis.                     |
| Magnetotaxis  | Earth’s magnetic fields | Motile, aquatic bacteria      | Orient and swim along magnetic field lines.                                    |
| Phonotaxis    | Sound                   | Crickets                      | Females are attracted by the male’s song                                       |
| Phototaxis    | Light                   | Dung beetle larvae            | Burrow into dung and away from the light                                       |
| Rheotaxis     | A current in water      |                               | Hold position in a current.                                                    |
| Thermotaxis   | Temperature             | Mammals                       | Seek warmth to maintain body temperature                                       |
| Thigmotaxis   | Physical contact        | Rats and mice                 | Will gravitate toward a wall or object and maintain contact with that surface. |

The classic example is the grey-lag goose. The graylag goose is a ground-nesting bird. If an egg becomes displaced from the nest, the parent goose will attempt to roll the egg back into the nest. The egg itself is the releaser stimulus for the FAP of reaching out and pulling on the egg with the beak. Unfortunately, eggs are not perfectly round and as such tend not to roll in a straight line. The egg will wobble slightly to the left or right. The unpredictable behavior of the egg serves as a releaser stimulus to make slight head tilts on the part of the goose to realign the egg's path toward the nest. This is a form of taxis: directional adjustment of the head to accommodate the movement of the egg. Together, the FAP of egg-pulling combined with the taxis of head and beak adjustments will successfully return the egg to its proper place in the nest (Fig. 7).

### Kinesis

Kinesis, like taxis, refers to movement of an organism (or cell) in response to an external stimulus. Kinetic movement, however, is non-directional; it usually involves the speeding or

slowing of locomotion, a shift from rest to movement, or the frequency or rate of turning. The animal does not move toward or away from the stimulus. Instead, the environmental stimulus, which is often associated with a suboptimal environmental condition, results in a change in general movement patterns. In a nutshell, organisms in optimal environments tend to stay put; organisms in suboptimal environments tend to move around until they stumble onto something better.

Many of us have witnessed the “flopping-about” behavior of a fish in the bottom of a boat. The behavior is clearly nondirectional. The absence of water and oxygen causes the kinetic movement that will continue as long as the fish has sufficient energy and resources to move, or until the environment dramatically improves. But with enough wriggling and a bit of luck, the fish may flop out of the boat and become “the one that got away.”

Kinesis is seen from single-celled organisms to complex animals. The classic example of kinesis (Gunn 1937) can be found in the wood louse (*Porcellio scaber*). In an optimal environment that

**Innate Behaviors, Fig. 7** Greylag goose fixed action pattern (FAP) of egg pulling is one part of a synthesis of FAP and taxes (head and beak adjustments) needed to return the egg to the nest. (After K. Z. Lorenz and

N. Tinbergen (1939). Greylag Goose and Egg rolling. K. Z. Lorenz and N. Tinbergen (1939) *Zeitschrift für Tierpsychologie*, 2, 1–29)

provides sufficient humidity, the wood louse is quiescent. However, as humidity declines, the louse begins to move rapidly about its environment. If the louse should stumble upon a more humid, more ideal environment, it will gradually become still. Failure to encounter a sufficiently humid location, the louse will become dehydrated and die. This sensitivity to humidity is called *hygrokinesis*.

There are two types of stimulus-driven kinesis; often they work in tandem, altering speed and direction as a single kinetic movement.

*Orthokinesis* refers to changes in locomotor speed that depends on stimulus intensity. Increasing locomotor speed is called *positive orthokinesis*; a decrease in speed is referred to as *negative orthokinesis*. Unlike taxes in which positive and negative describe directional movement in relation to the releaser stimulus, the same terms imply no such directionality with orthokinesis. Rather they refer to the acceleration or deceleration of the movement only. Examples of orthokinesis include woodlice, lamprey larvae (*Lampetra planeri*) that are more active in high intensity light environments, and cockroaches (*Periplaneta americana*) that are more active in the dark. Think of the cockroaches that shun the kitchen floor in the daytime, only to congregate there late at night.

*Klinokinesis* is a form of kinesis wherein the frequency or rate of directional change (or turning) is proportional to the intensity of the stimulus. Frequent changes in direction in response to increases in light (*photokinesis*) have been classically described in the flatworm (*Dendrocoelum lacteum*) by Ulliyott 1936, and in planeria (Reynierse et al. 1969). In large animals, an example of kinesis can be observed in dogs that circle repeatedly prior to laying down. If the bed does not provide ideal stimulation, the dog will continue to circle until the substrate is more suited to the dog's comfort. The dog is not moving closer to the bed, rather the dog circles and each turn slightly changes the substrate. Only when the bed is acceptable/optimal, does the dog actual lie down to sleep. Whether you are talking about the dog bed from your local pet store or grass for ancient wild dogs, the concept is the same. The suboptimal substrate serves as the stimulus that

initiates kinetic circling that continues until the substrate is more optimal. One might even draw similarities between the dog circling behavior and human "tossing and turning" behavior before we falling asleep.

## Innate Releasing Mechanism

Wendy A. Williams  
 Department of Psychology, Central Washington  
 University, Ellensburg, WA, USA

## Synonyms

[Releaser stimulus](#); [Sign stimulus](#); [Supernormal stimulus](#)

## Definition

Releaser mechanisms describe the relationship between a releaser stimulus (aka sign stimulus) and an innate behavioral response; these stimulus-response relationships exist within reflexes, fixed and modal action patterns, taxis, and kinesis.

## Releaser Mechanisms

The term *releaser mechanism* refers to an innate, biological relationship between an external sensory stimulus and a specific innate behavior. This relationship tends to remain invariant within a species, although it may be limited by maturity, sex, or hormonal status. For example, many innate behaviors are limited to only males, or only infants, or only occur during the breeding season.

All innate behaviors (including reflexes, fixed and modal action patterns, taxis, and kinesis) are elicited by these very specific stimuli called releaser stimuli or sign stimuli. Those releasers associated with reflexes, taxis, and kinesis are typically simple environmental stimuli that produce a similarly simple response. For example, a light shone into the eye results in reflexive pupil constriction, bees will innately fly toward a light source, and a fish out of water will flop about wildly until they accidentally flop out of the boat. These releaser mechanisms (e.g., the light, the lack of oxygen, etc.) are relatively simple and involve involuntary responses to the environmental stimulation.

Fixed or modal action patterns also rely on releaser stimuli and are equally involuntary. Although they may appear more complex, the relationship between releaser and behavior is similarly fixed. Familiar action patterns include vocalization exchanges, courtship rituals, or food caching. Releasers may be the presence of potential competitors, mates, nesting materials, or food items.

The terms *releaser stimulus* and *releaser* may be used interchangeably. A releaser stimulus is defined as a single feature of a complex stimulus array that will initiate an innate response. The term *sign stimulus* refers primarily to stimuli that are associated with fixed and modal action patterns. The relationship between the releaser or sign stimulus and the innate response is believed to be the result of evolutionary processes; the behaviors are often closely aligned with survival or reproduction. Responding to the releaser requires little or no cognitive engagement; the stimulus is presented and the response or response sequence follows – often all the way through to

completion in the case of action patterns. In the case of reflexes, the stimulus-response relationship may occur at the level of the peripheral nervous system long before awareness of the response is registered, such as with the patellar or knee jerk reflex. But even more complex behaviors, such as fixed and modal action patterns, are equally fixed and rigid, so much so that, in some cases, interruptions that should render the behavior completely ineffective may not be sufficient to disrupt the behavioral sequence (Eibl-Eibesfeldt 1970). An example of the rigidity of the stimulus-response relation in a model action pattern is egg case spinning in spiders.

Eibl-Eibesfeldt (1970) described the rigidity of egg case spinning in the tiger wandering spider (*Cupiennius salei*). After creating a base plate with a rim, the female spider lays her eggs and then closes the egg case. If the process is interrupted and the base plate is removed, the female will begin another attempt but without respinning the base plate beyond a few threads. The bottom of the new egg sac remains open, and the eggs laid will either fall through or not be protected. Eibl-Einsfeldt also observed that when the silk gland dried up (under hot filming lights) and no silk was available, the female spider

continued the behavioral sequence (as if spinning the base plate) and then laid her eggs in mid-air. For the spider, the urgent need to lay her eggs provides the necessary stimulation to proceed with her egg sac weaving behaviors, despite being completely unaffected by the failure of her efforts.

Table 1 lists a few examples of releasers and their corresponding innate responses across reflexes, taxis, kinesis, and action patterns.

Some sign stimuli are explained in terms of communication in that they transmit important information between individuals and which may elicit behaviors that directly affect survival and/or reproductive fitness. Tinbergen (1951) coined the term “social releaser” to describe such stimuli that influence the behavior of other animals.

Intraspecific Sign Stimuli

Releaser mechanisms can be important between members of the same species, especially where courtship and reproduction are concerned. Innate responses to specific morphologic features or stereotyped behavior patterns can greatly influence whether or not an individual finds a mate and successfully raises their offspring.

**Innate Releasing Mechanism, Table 1** Releasers associated with various innate behaviors. Examples include reflexes, taxis, kinesis, and fixed or modal action patterns

| Type of behavior     | Releaser stimulus                                        | Behavior                                                             | Species                       |
|----------------------|----------------------------------------------------------|----------------------------------------------------------------------|-------------------------------|
| Nursing reflex       | Nipple in the mouth                                      | Suckling                                                             | Most mammals                  |
| Patellar reflex      | Tap on patellar tendon                                   | Knee jerk                                                            | Most mammals                  |
| Coughing reflex      | Irritation of the trachea                                | Coughing                                                             | Mammals, birds                |
| Phototaxis           | Light                                                    | Approach or avoidance of light                                       | Jellyfishes, insects          |
| Rheotaxis            | A stream’s current stimulates the lateral line           | Facing into or moving away from the current                          | Fishes                        |
| Thigmotaxis          | Open field                                               | Maintain close physical contact with a physical object (like a wall) | Rodents                       |
| Orthokinesis         | Increased humidity                                       | Increase locomotor speed                                             | Woodlice                      |
| Klinokinesis         | Increased light                                          | Increased turning                                                    | Flatworms                     |
| Modal action pattern | Red belly of competitor males during the breeding season | Aggression in the resident, breeding male                            | Three-spined stickleback fish |
| Modal action pattern | Presence of a female during the breeding season          | Male courtship dances                                                | Insects, birds, fishes        |

**Red belly of the three-spined stickleback fish.** Perhaps the most familiar example of a sign stimulus occurs in the three-spined stickleback fish (*Gasterosteus aculeatus*). The male stickleback establishes and defends a breeding territory. During the breeding season, the male builds a nest in the river substrate. When the nest is complete, the male stickleback then begins to exhibit various aggressive and defensive territorial behaviors and ritualistic courtship behaviors in response to specific sign stimuli: the presence of other breeding males or receptive females.

From late March to early August, breeding males' bellies turn red as they set up territories and build their nests. When intruder male with a red belly enters a resident male's territory, he is met with the erection of the three spines on the dorsal side of the resident fish (a reflex), and modal action patterns include aggressive rushing and biting that will continue until the intruder male leaves the territory. In a classic study looking at the stimuli that produce these aggressive behaviors, Tinbergen (1951) used clay models of various shapes to determine the nature of the sign stimulus (see Fig. 1). He found that almost any shape of clay would suffice to elicit aggressive behavior as long as the ventral side of the clay was painted red.

**Innate Releasing Mechanism, Fig. 1** A breeding three-spined stickleback male, and a clay model (aka sign stimulus) similar to those used by Tinbergen to elicit aggression from competing males during the breeding season. Males responded to various clay shapes as long as they had a “red belly.” (Image taken from Behavioral biology: Figure 1 by OpenStax College, Biology, CC BY 4.0)

**Red spot on the herring gull's beak.** In another study using models, Tinbergen and Perdeck (1950) investigated the stimulus associated with feeding responses between herring gulls and their chicks. In the wild, herring gull chicks peck at a red spot on the parent bird's bill as food solicitation. When the chick does so, it stimulates food regurgitation in the parent. Tinbergen manipulated the appearance of the red spot using realistic models of herring gulls with a red spot, as well as artificial models, some reduced to a simple pencil-like shape with alternating red and white bars on the tip. Tinbergen found that although the realistic model did elicit pecking by herring gull chicks, those models did not produce the most vigorous responses. The pencil-like stimuli with greater than normal length and more red than normal produced the most robust responses (see Fig. 2).

## Interspecific Sign Stimuli

Sign stimuli can influence interactions between species as well. Morphological releasers may alter the behavior of a predator or competitor through mimicry.

**False eyespots in moths and butterflies.** Some members of the genus *Lepidoptera* (butterflies and moths) have evolved false eyespots on their wings that are similar to owl eyes (see Fig. 3). When threatened by predatory birds and mammals, the moth will spread its wings and expose the spots. The innate response by certain insectivorous predators is to flee from anything resembling the eyes of their own predators, such as an owl. Similar evidence exists for fishes (Karplus and Algom 1981). Often used an example of the “escalating arms race” between predatory and prey, the evolution of false eyespots in moths and butterflies demonstrates the importance of interspecific sign stimuli. Recently, a study of over 70 species of moths and butterflies (*Lepidoptera*) have shown that the level of detail in these false eyes spots includes a white highlight called a “sparkle” which appears to enhance the deterrent effect of the spot (Blut et al. 2012).

**Innate Releasing Mechanism, Fig. 2** Different herring gull beak models used by Tinbergen and Perdeck (1950) to demonstrate the key features of sign stimulus control on pecking in young chicks. **Innate Releasing Mechanism, Fig. 3** False eyespots in the moth *Automeris*. Note the sparkle of white in the fake eyes. This increases the false eye's deterrent value. (Photograph taken by Patrick Coin, CC BY-SA 2.5, <https://commons.wikimedia.org/w/index.php?curid=768361> Wikimedia Commons)

## Supernormal Stimuli

Unlike experiments that reduce the characteristics of a sign stimulus to their minimally essential features (e.g., the clay models of the three-spined stickleback fish), a supernormal stimulus is an artificially altered sign stimulus – often made

larger, brighter, or more salient to test response strength or bias. By exaggerating certain characteristics of a sign stimulus, innate responses are similarly exaggerated and, often, nonadaptive. Birds, for example, may show a strong preference for an unusually large egg – one that they could not physically lay. How could this odd, non-adaptive bias evolve?

One explanation is that natural selection has favored naturally larger eggs. Larger eggs produce larger, more robust offspring, and so those avian parents who invest care in the larger egg are more likely to produce offspring that are more likely to survive. Favoring the larger egg increases one's reproductive fitness when it results in more offspring who live long enough to reproduce themselves. But viable body size of the parent is determined by resource availability and leads to an upper limit in bird body size. Since birds can only get so big, eggs' size too is limited – but not by behavioral choice. If eggs become too large, the parent simply may not survive, and her genes are removed from the gene pool. If the environment restricts the upper limit of bird size, then it is advantageous for the female to choose the largest eggs she can possibly lay. Natural selection favors the “choose large” strategy because there is no selection mechanism that could favor choose a “large but not too large” strategy. The result is a strong, positive behavioral bias that can be tested by presenting the female with an unnaturally large egg. Because the species has never faced selection pressures for “don't choose too large,” that component has never become part of the equation. Not all bird species exhibit the “choose large” strategy. Evolutionary stable strategies depend on various factors. But for some bird species, like warblers and oystercatchers (see Fig. 4), choosing the large egg is a strong bias. In the case of the warbler, it is so strong that it puts them at risk for brood parasitism.

The cuckoo bird (*Cuculidae*) is the classic example of a brood parasite; they have evolved a nesting strategy that takes advantage of the “choose larger eggs” bias in other birds. Cuckoos, and other brood parasites like the cowbird, lay their own large eggs in the nests of other smaller bird species, including warblers, vireos, and

**Innate Releasing Mechanism, Fig. 4** An oystercatcher choosing to sit on an unnaturally large, supernormal egg over a normal egg. (Adapted from Tinbergen 1951)

buntings (King 1954). The cuckoo's eggs are often similar in appearance to the host bird's eggs but larger. Host parents typically do not object to the unusually large egg in their nest and will continue to brood it along with its own eggs. The exaggerated size of the egg elicits parental care that favors both the large egg and the resulting chick; often resulting is the loss of their own offspring. Other brood parasitic birds include indigobirds, whydahs, honey guides in Africa, and North American cowbirds. For more information, see "Brood Parasitism."

## Sign Stimuli in Humans

There is mixed opinion on whether sign stimuli exist for humans. Conrad Lorenz suggested that baby animals of many species share a "babyishness" with human babies – large eyes, bulging foreheads, and small chins (see Fig. 5). He suggested that this baby-like appearance tends to elicit certain parenting or nurturing behaviors like affection toward baby animals as well as human babies.

Contagious yawning has also been suggested as an example of a social sign stimulus in humans. The observed yawn serves as the releaser stimulus for the elicited yawn in the observer. Contagious yawning has been confirmed experimentally by Provine (1986), who found that 55% of subjects yawned after viewing a 5-min series of 30 yawns. However, the conventional definition of a sign stimulus typically states that all members of the species respond to the stimulus in a similar way. Most human examples do not fit this definition.

**Innate Releasing Mechanism, Fig. 5** "Humans feel affection for animals with juvenile features: large eyes, bulging craniums, retreating chins (left column). Small-eyed, long-snouted animals (right column) do not elicit the same response" (Lorenz 1971). (Animal human growth skull neoteny cuteness maturation.png taken from <https://creativecommons.org/licenses/by-sa/4.0/>)

## Limiting Factors

Finally, it is important to note that some releaser stimuli do not exert their influence independent of context. The effect of a releaser may depend on the context in which it appears. A male stickleback fish will aggress on another male if the intruder enters the resident fish's breeding territory. But the same competitor may cause other males to flee if encountered outside their own territories (Fantino and Logan 1979). The context is key in determining the response elicited by the sign stimulus. Similarly, seasonality may also play a role in determining the effect of a releaser stimulus. The European robin, harbinger of spring, will sit at the top of a tree and sing repeatedly in response to the songs of other robins. The rest of the year, robins are not known for such robust singing.

## Introduction: History and Definitions

A Barbados bullfinch, *Loxigilla barbadensis*, lands on a table at a coffee shop, flips over a sugar packet, and, after piercing it with its beak, feeds on the sugar. A bottle-nose dolphin (*Tursiops* sp.) in the Shark Bay, Australia, removes a marine sponge from the substrate and wears it over its rostra as it probes the rough seafloor. A New Zealand kea (*Nestor notabilis*) skillfully topples over a trash bin lid, gaining access to the food scraps within. The apparent ability of nonhuman animals to develop novel solutions to the challenges of everyday life is a constant source of delight for the broader public and one of the constant scientific enquiries for scholars. Behavioral innovations, defined as novel behaviors or preexisting ones used in novel contexts, are now recognized as a key source of behavioral plasticity and, as such, have become central to our thinking of how animals adjust to novel and changing environments.

While one can reasonably expect behavioral innovations to arise in a variety of functional domains, most of what is known about innovation in nonhumans relates to the foraging domain. In the late 1990s, Louis Lefebvre and his colleagues from the University of McGill, Canada, published a series of keystone contributions that led to an explosion of research on the topic. Using a readily available large body of low-impact ornithological publications, Lefebvre and his co-workers counted for each avian species the number of anecdotal reports of novel and unusual feeding behaviors in the wild (Lefebvre et al. 1997, 1998). Over the last decade, these taxon-level, field-based “innovation counts,” or “innovation rates,” when corrected for brain-body allometric relationships, have been related to a large number of morphological (e.g., brain size), ecological (e.g., migratory status), and evolutionary parameters (e.g., taxonomic radiation) and have been used to investigate the adaptive value of animal innovations and their evolutionary consequences (reviewed by Lefebvre (2011)). Therefore, it is now relatively well established that foraging innovations facilitate invasion of novel habitats (Sol et al. 2002, 2005), enhance survival in harsh (Sol et al. 2005) and variable environments (Sayol

et al. 2016), and accelerate taxonomic radiation (Nicolakakis et al. 2003). More recently, experimental research has explored the attributes of innovative individuals, the contextual factors that facilitate innovation, and the psychological mechanisms that underlie the expression of innovative behavior (Griffin and Guez 2015; Griffin et al. 2013; Morand-Ferron et al. 2011). For this, researchers have developed a paradigm known as “innovative problem solving” or just “problem solving.”

### Problem Solving: The Paradigm

In stark contrast to methodologies established in the ecological approach to the study of animal cognition, which has emphasized the need to test animals in ecologically meaningful contexts, causal analyses of animal innovations have drawn upon the experimental principle of presenting animals with novel problems they are unlikely to have encountered in their natural environment. Usually, novel problems involve some kind of extractive foraging task with which subjects need to interact to gain access to food. Innovation propensity is then gaged by measuring their ability (latency, success) to solve it. Recently attempts have been made to find an alternative motivator than food and used problems that animals need to solve to gain access to their nest (Cauchard et al. 2013) or to improve their sexual displays (Keagy et al. 2011). Interindividual variation in performance is then related to individual attributes (e.g., sex, age); alternatively, the effects of manipulating context on performance are examined (e.g., group size). Also of interest has been whether specific problem-solving techniques spread through groups and even through free-ranging populations seeded experimentally with trained problem solvers (Aplin et al. 2015). Tasks generally involve a one-stage solution, but the use of multistage tasks has become more common within the context of quantifying to what extent animals reason about the consequences of their actions on the problem at hand and the causes of their success and failure (Huber and Gajdon 2006; Taylor et al. 2009).

One can reasonably wonder to what extent anecdotal reports of innovations in the wild and experimental measures of innovative problem solving quantify the same behavioural trait. Demonstrating the convergent validity of behavioral tests is by no means an easy task, but several studies in free-ranging birds have found that the taxonomic distribution of innovation counts overlaps with the taxonomic distribution of problem-solving performance (Diquelou et al. 2016; Webster and Lefebvre 2001). Species that belong to the Corvidae family (e.g., crows) have high innovation counts and perform well on problem-solving tasks, whereas species belonging to the Columbiformes (e.g., doves) have few innovation counts and tend to perform poorly, with Passerines (e.g., starlings) occupying the middle ground on both measures. Recently, Griffin and Guez (2014) attempted to evaluate the convergent validity of problem solving and innovation counts by examining whether factors predicted and demonstrated to cause and influence innovation counts also cause and influence problem solving. They concluded that in most respects, problem solving is determined by the same underpinning mechanisms and is influenced by the same factors as those predicted to underpin and influence innovation, providing additional evidence of convergent validity.

### Problem Solving: Who Are the Innovators?

Spurred along by a strong history of relating field-based innovation counts to taxon variation in relative brain size and finding that avian and primate taxa with higher innovation counts had larger brains relative to their body size, much of the initial work on problem solving argued for a strong relationship between problem solving and cognitive performance. Since then, a variety of other potential individual attributes has been considered with a particular focus on factors that alter the likelihood that an animal will make contact with a novel situation in the first place. Following the natural sequence in which behavior occurs (i.e., approach must occur prior to deployment of

any cognitive ability), this section will first introduce the factors that determine contact, followed by what is understood about the role of cognition. Finally, focus will be put on the results from recent work that has explored the role of motor flexibility in problem solving.

### Are Innovators Particularly Motivated or Exploratory?

One possibility is that individuals that innovate tend to be particularly motivated to solve the problem at hand. Motivation has been evaluated by quantifying the persistence with which an individual engages with the (typically foraging) problem (e.g., beak-to-task contacts) (reviewed by Griffin and Guez 2014) or by using proxies collected outside the problem-solving context (body weight, body fat, body condition) (Griffin et al. 2014). Perhaps unsurprisingly, individuals that engage more with the problem at hand are more likely to solve it and solve it more quickly than individuals that engage less with the task. For example, both great tits (*Parus major*) and blue tits (*Cyanistes caeruleus*) are more likely to solve an extractive foraging task the more time they spend it its proximity and the more they have tried (Morand-Ferron et al. 2011). Experimental manipulations of motivation, such as food deprivation, also enhance problem-solving performance (Griffin et al. 2014). There is little evidence, however, that assumed proxies of motivation collected outside the task moderate problem-solving performance. For instance, Cauchard and co-workers (Cauchard et al. 2013) found that the time taken by great tit parents to remove an obstacle to access their nest had no bearing upon how frequently they fed their nestlings. Morphological proxies for motivation (e.g., body condition) are also unrelated to problem solving.

Another option is that innovators are those individuals that are more willing to approach and interact with novel situations. They are more innovative simply because they come into contact more frequently with novel situations in which they can invent a novel behavior or to which they can apply a preexisting behavior. Innovators are then simply individuals that are less wary of

novelty, perhaps even more attracted to novelty, and in that sense more exploratory. So far, evidence for this hypothesis is mixed. In some studies, innovators are less fearful of novelty and more exploratory, supporting the hypothesis, while in others, there is no relationship between innovation performance and these behaviors (reviewed by Griffin and Guez (2014)). Differences in the way these responses are measured might be the reason behind inconsistent results.

### Are Innovators More Intelligent?

The finding that avian and primate taxa with larger relative brain sizes have higher innovation counts has been taken to mean that innovations represent the behavioral expression of greater cognitive endowment (but see Healy and Rowe 2007). Given that interindividual variation in a given trait provides the raw material upon which selection acts to drive the evolution of variation at higher levels, researchers set out to find interindividual variation in innovation propensity with the expectation that these should correlate with interindividual variation in cognition. Most often, individual performance ranks on innovation tasks (most often solving latencies) have been correlated with individual performance ranks on learning tasks (typically acquisition speed or errors) to investigate whether more innovative individuals are also those that learn faster or more accurately (reviewed by Griffin and Guez 2014). Given the view that innovations are linked to general cognition, learning has been quantified in the context of tasks assumed to measure “general” learning abilities, including operant and classical conditioning, rather than learning abilities considered to be more modular, such as song learning and spatial learning.

To date, five of six studies using operant learning as a measure of cognition have found that innovation propensity and learning covary. For example, in European starlings (*Sturnus vulgaris*), pigeons (*Columbus livia*), and Carib grackles (*Quiscalus lugubris*), birds that solve an innovative problem-solving task in a shorter amount of time acquire a novel foraging technique faster (e.g., flipping a lid on a container) (Boogert et al. 2008; Overington et al. 2011). Although

these studies provide tentative support for the idea that innovative behavior is linked to at least one facet of cognition (operant learning), they are not designed to exclude the possibility that associations between innovation and learning might be the result of associations between the rates at which novel information is encountered (via activity/exploration) rather than correlations in the capacity to process and store environmental information per se (i.e., cognition).

Pavlovian learning and reversal learning tasks, which assess more accurately how fast an individual acquires environmental information over and above how often it encounters opportunities to learn, have yielded much more mixed results than those using operant learning. Common mynas (*Acridotheres tristis*) that take longer to discover the solution to an extractive foraging task learn a Pavlovian association more quickly; however, these individuals also learn more slowly the new state of the world when that association is altered (i.e., reversal learning; Griffin et al. 2013). In another mixed set of findings, Carib grackles (*Quiscalus lugubris*) that discover the solution to one extractive foraging task more quickly learn a Pavlovian association more slowly, whereas how fast the birds find the solution to an alternative task bears no relation with their Pavlovian learning speed (Ducatez et al. 2014).

Perhaps the most robust approach to evaluating the relationships between innovation propensity and cognition at the interindividual level has involved testing animals on batteries of learning tasks and then using a principle component analysis to extract a “general learning factor” whose correlation with innovation performance can be examined. Most promisingly, spotted bowerbirds’ (*Ptilonorhynchus maculatus*) problem-solving performance loads positively, albeit weakly, on to the same principle component as a general learning factor (Isden et al. 2013).

Up to now, consideration has been given to whether cognitive abilities correlate with innovation propensity. For cognitive processes to be a *causal* determinant of innovation (i.e., solution discovery in a problem-solving task), animals must have (1) the capacity to select specific motor actions before using them based on prior

knowledge and/or (2) the capacity to “hone in” on the solution until solving occurs for the first time. New Caledonian crows (*Corvus moneduloides*) are capable of goal-directed solving in that they have been shown to extract and store functional properties of objects and apply them to other problem-solving opportunities (Taylor et al. 2009). Establishing these capacities generally involves training test subjects extensively prior to establishing whether they carry over acquired knowledge to solving yet other novel problems. When suitably designed, these tests disentangle the roles of causal reasoning from those attributable to associative learning processes. Given their complexity and the extensive training often involved prior to spontaneous problem solving, less clear is the extent to which such tasks reproduce a suitable context to the study the mechanisms of avian innovations more generally. This is particularly so when these include seemingly simple novel foraging patterns such as removing caps from milk bottles, catching insects on the wing, foraging for prey by artificial light, or digging for prey in sand (Lefebvre et al. 1997, 1998).

Rather than causal reasoning, perceptual rules offer an alternative mechanism by which animals can appear to select a motor action prior to using it. Perceptual rules, such as making preferential contact with object edges, with areas of high visual contrast, or protruding surfaces, could guide animals’ interactions with objects. Such rules might be acquired as a consequence of experience of past pairings with rewards (e.g., pecking the edge of an object is more likely to break/move it than pecking its center) or might have become genetically assimilated in those species that routinely interact with objects. Such rules would remain tightly bound to the perceptual attributes of objects but would nevertheless assist animals in solving innovation tasks without assuming that they have any understanding of how solutions work.

Gradual honing in on a solution occurs when an animal learns that a particular motor action is associated with a secondary cue indirectly paired with reward delivery. For example, Carib grackles discover the solution to an extractive foraging task faster when parts of the device are made to move

in response to actions by the bird than when these movements are blocked (Overington et al. 2011). This finding suggests that movement stimuli might act to increase the likelihood that the “successful” motor action is repeated. This is a learning process that is most often referred to as “shaping.” Another possibility is that secondary cues increase the likelihood of the animal perseverating, that is, of attempting again to solve, independently of which motor action is used. This is not a learning process because no association is formed between a particular motor action and a secondary cue. The hallmark of a learning process is a gradual narrowing in motor frequencies with motor actions that produce secondary cues that are increasing and those that are not decreasing; changes in perseverance will be characterized by increases in the number of attempts without changes in the frequencies of which motor actions are expressed.

## Motor Flexibility

Many instances of innovation involve the expression of a behavioral variant, namely, a behavior that deviates from the individual’s or population’s behavioral norm. These might be completely novel or small variations of existing motor actions. With this in mind, it seems reasonable to assume that an individual or species with a larger, more diverse, motor repertoire is likely to express more motor innovations. In most published data sets, motor diversity is conceptualized as a greater number of distinct motor actions or number of areas contacted (e.g., Benson-Amram and Holekamp 2012; Griffin et al. 2014; Overington et al. 2011). More recently however, researchers have developed an index that takes into account both the number of different motor actions and the relative frequency with which they are expressed (Diquelou et al. 2016; Griffin and Diquelou 2015). Both a higher number of actions expressed, and even probabilities of each one occurring, serve to raise motor flexibility. Several studies have now shown that motor flexibility explains a significant proportion of interindividual and interspecies variation in innovative problem solving

(Benson-Amram and Holekamp 2012; Diquelou et al. 2016; Griffin et al. 2014; Overington et al. 2011).

To simulate the effects of motor flexibility on problem solving, Guez and Griffin (2016) recently developed a computational model to examine the combined effects of motor flexibility, learning, and persistence on problem-solving performance by a hypothetical agent. First, an agent was assigned four possible motor actions, with only three leading to task solving. The probability of expression of each motor action was either skewed toward one motor action to simulate low motor flexibility or evenly distributed between the four motor actions to simulate the effects of high motor flexibility. Guez and Griffin (2016) then integrated the effects of learning by allowing expression probabilities to change each time a secondary cue occurred, whereas changes in persistence in response to secondary cues were simulated by making another attempt more likely. The simulations revealed a positive effect of learning on problem-solving performances in cases where secondary cues were very common and the change in motor frequencies each time a movement cue occurred were very large. In most other modeled scenarios, increases in persistence improved problem solving more than learning. These simulations suggest that problem solving might often be caused by a combination of motor flexibility combined with changes in perseverance induced by secondary cues, placing variation in innovativeness at the individual level firmly within the realm of random motor variation rather than any variation in information processing capacity.

## Conclusions

Avian innovation counts are thought to provide a direct measure of cognition. Some researchers have gone a step further to assert that interindividual variation in innovation propensity is a measure of cognitive ability. A small body of evidence suggests that innovation propensity is a repeatable individual attribute. However, this interindividual variation appears not to be reliably

associated with interindividual variation in learning in either empirical work or simulations. In contrast, task-directed motivation and motor flexibility are more reliably associated with innovative problem solving. Interindividual variation provides the raw material for the evolution of cross-taxon differences. How then can the consistently positive associations between cognition and innovation found in the cross-taxon comparisons be reconciled with the mixed patterns of associations between innovative problem solving and learning performance at the within-species level? It has been argued that cognition and innovation might share a correlational rather than causal relationship (Griffin and Guez 2016). In other words, these phenotypes might covary at the cross-taxon level, not because cognition causes innovation but rather because, as suggested by theories of brain and cognitive evolution and environmental models of diet generalism, both cognition and diet diversity undergo evolutionary selection under conditions of environmental variability. However, it is diet diversity, via its effects on motor diversity, that drives innovativeness and not enhanced cognition. Only future research will tell.

[Animal communication](#); [Information theory](#);  
[Information transmission](#); [Signaling](#)

## Definition

Exchange of information between a sender and receiver in insects

## Introduction

Broadly, communication refers to any exchange of information between individuals. The individual transmitting the information is the “sender,” while the individual to whom the information is transmitted is the “receiver.” The sender can be a single individual or a group of individuals, just as the receiver may be an individual or a group of individuals. Often, the information transmitted is meant to influence the current or future behavior of the receiver. This information is referred to as a “signal”; the sender is the “signaler.” Theory predicts that for a signal to evolve, both the sender(s) and receiver(s) should benefit from their interaction (Bradbury and Vehrencamp 1998). Thus, there should be tight coevolution between signal production and subsequent perception and response.

Insects communicate in various contexts, both between and within species. These contexts include but are not limited to mate choice, competition with conspecifics for access to mates, avoiding predators, locating resources, and kin recognition.

**Mate choice:** Individuals (typically males) attempt to attract potential mates with conspicuous visual displays, sounds, and smells. The

responsive sex (typically females) can respond to mating advances with similar displays of their own.

**Competition:** Individuals signal to others in agonistic interactions to secure mates, territories, or other resources.

**Predator avoidance:** Insects send alarm signals to warn others against nearby predators or warning signals to deter predators themselves.

**Resource localization:** Members of the same species or colony share information about accessing food and other resources.

**Kin recognition:** Some signals are species- or kin-specific and allow insects to identify intruders, avoid inbreeding, and prioritize the safety of close kin.

## Modalities of Insect Communication

**Visual signaling** involves the display of distinct body parts, typically referred to as the signal. Of all insects, butterflies, flies, dragonflies, and damselflies use visual signals most often.

**Mate choice:** Many insects use visual signals, especially colorful wings, to attract mates. The red admiral butterfly, *Vanessa atalanta*, uses bright coloration on the dorsal wing surface that gains the attention of potential mates.

**Predator avoidance:** The ventral side of the aforementioned red admiral butterfly is drab, camouflaging the species from predators (Opler and Krizek 1984). Some insects have bright advertisement signals, called *aposematic signals*, that warn predators of their unpalatability (Mappes et al. 2005). Lady beetles, tiger moths, and blister beetles all broadcast long wavelength colors like red and orange colors that advertise the bitter-tasting chemicals in their bodies. Many butterfly and moth species have large round eyespots on their wings. In some cases, these spots mimic the eyes of another, potentially more dangerous animal. For example, *Hemeroplanes triptolemus* larvae expand the front segments of their bodies, mimicking a snake and scaring off predators. Otherwise, the spots encourage a predator to attack a part of the insect's body that is less vital to its survival. When a predator attacks, it will go for the

eyespot located on the wings, avoiding the thorax or abdomen.

**Resource localization:** One of the biggest discoveries in animal communication is that honeybees, *Apis mellifera*, use visual communication to share information about nearby resources. These bees use two forms of dance behavior, the waggle dance and the round dance, that share information with other members of the colony about the direction and distance to patches of flowers yielding nectar and pollen, water sources, or new nest-site locations (Riley et al. 2005). As the distance between the resource and the hive increases, the round dance transforms into variations of a transitional dance, which, when communicating resources at even greater distances, becomes the waggle dance (Seeley et al. 2006).

**Kin recognition:** Visual signals can be used to identify individuals living among a group. Paper wasps, *Polistes fuscatus*, have highly variable yellow facial and abdominal markings that are signals of individual identity. Queens and workers form a linear dominance hierarchy that determines how food, work, and reproduction are divided within the colony. This stable hierarchy is facilitated by individual recognition between the different ranks (Tibbets 2002).

There are many advantages to visual signals. This form of communication is long range and effective in all directions, regardless of wind speed. Since visual signals travel at the speed of light, they are the fastest of all signaling types. If the signal is passive, like many aposematic signals, they require little to no energy to broadcast. There are some disadvantages to visual signaling, such as the requirement for the receiver to have a clear view of the signaler. Since visual signals are only effective when they are visible to the receiver, many insects display only when the sun is out. *Bioluminescence* is an exception to this rule, where some insects such as adult *Photuris* fireflies, glowing click beetles and cockroaches, and railroad worm larvae produce their own light and signal at night. Lastly, active signals, like sexual signals, can be metabolically expensive to produce, and visual signals can be broadcast to unintended receivers like predators who can more easily spot prey adorned with these elaborate signals.

**Acoustic signaling** involves the production and propagation of sound toward a receiver. In the absence of the vocal structures reserved to vertebrates, insects have evolved diverse mechanisms for sound production. Crickets and katydids sing by stridulating or rubbing together specialized wing structures to generate pulses of sound (Alexander 1961). Similarly, grasshoppers rub their hind legs against hardened forewings, creating sound like a bow on a violin. Cicadas have specialized organs called tymbals that generate sound when flexed back and forth (Young and Bennet-Clark 1995). Several beetle species make sounds by rubbing body parts together or on an external source. For example, deathwatch beetles bang their heads repeatedly on hard surfaces to generate a ticking noise (White et al. 1993). Other insects, such as Madagascar hissing roaches, produce hissing sounds by expelling air through spiracles (Nelson 1979). Like other terrestrial animals, most insects use a thin membrane known as the tympanum to process sounds. Insect tympana can be located anywhere on the body, including the legs (crickets and katydids), wings (butterflies), mouthparts (sphingid moths), abdomen (cicadas), and thorax (tachinid flies, praying mantis) (Greenfield 2016).

*Mate choice and competition:* Male crickets, katydids, grasshoppers, and cicadas produce songs that attract females in mate choice. In some families (such as katydids), females may respond to mating attempts with songs of their own (Villarreal and Gilbert 2013). Males of these species can also employ sound in competition to establish dominance or warn other males not to approach (Alexander 1961).

*Predator-prey dynamics:* Sounds also play a role in predator avoidance and prey localization. For example, cicadas emit a distress call when disturbed, warning others of a potential predator (Young and Bennet-Clark 1995). Some moth species emit sounds that jam a predatory bat's echolocation sense (Corcoran et al. 2009). Predators and parasites such as tachinid flies use their exceptional hearing to find prey (Lehmann 2003).

Acoustic signaling provides several advantages for insects. Since sound is easily

manipulated, slight changes in sound characteristics (amplitude, frequency, periodicity) can produce a wide range of signals conveying different kinds of information. Sound waves also move relatively quickly to receivers. However, sound can be metabolically expensive to produce, and acoustic signals can often reach deadly targets such as predators and parasites. Sound also attenuates (reduces in intensity), and the strength of the signal is lost over long distances. In noisy environments, receivers may have trouble perceiving an acoustic signal.

**Chemical signaling** is one of the oldest and most common forms of insect communication. Insects regularly signal with **pheromones** (within species) and **allelochemicals** or **allomones** (between species) (Regnier and Law 1968; Ali and Morgan 1990). Many also use non-volatile, short-range hydrocarbons as chemical signals (Singer 1998). Individuals generally sense long-range chemical signals with olfactory reception and short range with forms of contact reception, such as taste. Chemical communication is most famously studied in group-living and social insects such as hymenopterans (ants, bees, wasps), aphids, and termites.

*Resource localization:* As picnic-goers often notice, ants use pheromone trails that lead nest mates toward food sources in a behavior known as *tandem running*. This behavior is also commonly found in termites, which lay chemical trails that facilitate group foraging (Kaib 2013). Solitary insects also use chemicals in resource communication; bark beetles use pheromones that convey the location of a new host tree to their conspecifics.

*Predator avoidance:* Termites, alongside social bees and wasps, also use alarm pheromones that recruit their kin into attacking predators (Kaib 2013). More defensively, several ant and aphid species employ chemical alarm signals that warn nest mates to scatter as a predator approaches (Yamaoka et al. 2006). Many solitary insects either exude unappealing scents or directly chemically incapacitate a predator. The aptly named brown marmorated stinkbug produces foul smells that deter its predators. Several beetles, flies, and moths use chemical repellants

in areas where they lay eggs to divert potential predators or competitors. Cockroaches secrete chemicals onto their dorsal side that harden like glue in a predator's mouth, allowing the roach time to escape (Farine et al. 2002). Bombardier beetles famously expel fatal chemical steam from their abdomens when threatened (Eisner 2003).

**Kin recognition:** The ability to recognize kin often facilitates an extreme division of physical and reproductive labor in social insects. Ants, social bees, and social wasps use colony-level chemical "profiles" to identify relatives and expel intruders without the same cues, avoiding exploitation by outsiders. Pheromones can also directly mediate the reproductive division of labor. Queen honeybees produce pheromones that both limit the development of ovaries in workers and attract drones (males) to mate (Hoover et al. 2003). These chemicals ensure that only queens reproduce in a colony.

**Mate choice:** In social insects, mating behavior is generally limited to the queen (ants and social bees), king (termites), and reproductive workers (semisocial wasps). There are few such limitations in solitary insects, where males and females alike use pheromones to attract and locate mates. When the chemical causes searching behavior, it is referred to as a *sex attractant*; when it induces mating behavior, it is called an *aphrodisiac*. Moth sex attractants are particularly well studied, as females release long-distance pheromones (30+ miles in some silkworm families) that signal availability to receptive males. In tiger moths, females select males based on pheromone production, which acts as an honest indicator of male fitness (Lofstedt 1993). In species with multiply-mating females, males use chemicals to ensure paternity. For example, tsetse fly sperm contains chemicals that act as an anti-aphrodisiac, discouraging other males from mating with a female (Carlson and Schlein 1991).

There are several advantages to chemical communication in insects. Most chemicals are highly effective in low doses, meaning that small quantities can provoke behavioral responses. Chemical signaling is therefore less metabolically expensive

than many other forms of communication. Chemicals do not degrade quickly or become harder to sense in different visual conditions; they are effective across long distances and many environments. However, since long-distance signals depend on air transmission, chemical communication may not be as effective if a receiver is upwind of a signaler. Chemical signals are also not as variable as acoustic signals, and thus do not carry as much information about the signaler. While less conspicuous than visual and acoustic signals, predators can still exploit chemical cues. For example, parasitoid wasps can mimic the scent of their prey to infiltrate habitats and lay parasitic eggs and larvae.

**Vibratory signaling** involves the use of low-frequency, substrate-borne (rather than air-borne) vibrations to communicate. Insects produce vibrations in diverse combinations of percussive drumming, tremulation or abdominal and body jerking, tymbal clicking, and stridulation.

**Predator avoidance:** Many termite species produce vibrational signals to warn nest mates of predator disturbances or pathogenic fungal spores in the nest (Kirchner 1997; Rosengaus et al. 1999).

**Resource localization:** Interestingly, vibrational communication plays a large role in the evolution of some *mutualisms* between different insect species. Larvae and pupae of ant-associated butterflies produce substrate-borne signals that attract high numbers of ants, thereby increasing their protection against predators (Travassos and Pierce 2000). Perhaps the best example of vibratory insect communication is in group-living treehoppers, which communicate almost exclusively using vibratory signals. Vibratory signals are associated with defense and parental care (Cocroft 1999) and are used to locate feeding sites (Cocroft 2001). Similarly, gregariously living sawfly larvae use vibrational signals that maintain colony cohesion and locate fresh food sources (Cocroft 2001).

**Mate choice:** Male treehoppers send vibrations that attract females, and responsive females will signal in return. Before mating, males and females will engage in vibrational duetting, with the male and female signaling back and forth. Some

crickets and katydids also use vibrations to attract mates.

Vibrations are an essential form of communication for many small insects. In order to effectively communicate with air-borne acoustic signals, smaller insects need to produce very high-frequency signals, which are prone to greater degradation (Bennet-Clark 1998). Thus, smaller insects use vibrational signals because they are far-reaching and relatively low cost. Propagation of vibrational signals is also less diffuse, and the signal is confined to the substrate through which it is being sent. Therefore, it is easier to locate, but less likely to attract aerial predators. As long as the continuity of the substrate is maintained, the transmission of a vibratory signal is not greatly affected by obstacles in its path. Substrate-borne communication has some disadvantages. Primarily, vibratory signals are distorted in time and frequency, and vibrations become more degraded with increasing distance between the signaler and the receiver.

**Multimodal communication**, or the use of signals in two or more modalities, is ubiquitous in insects. In fact, unimodal signaling may be the exception rather than the norm. These signals can either convey different messages about the signaler or redundant information to reinforce the impact of one message (Hebets and Papaj 2005).

*Resource localization:* Honeybees use visuals, vibrations, and chemicals in different parts of the waggle dance to elicit foraging behavior from their hive mates (Hölldobler 1999).

*Predator avoidance:* Wood tiger moths use both aposematic coloration and chemical signals to warn blue tits against eating them; the combination of signals is a more effective deterrent than either in isolation (Rojas et al. 2019). Similarly, some species of ants use a combination of vibrational tapping and alarm pheromones to warn hive mates of danger (Hölldobler 1999). Alarm chemicals are more effective than vibrations, but the combination has the most impact.

*Mate choice:* Male field crickets use both courtship songs and contact chemicals to attract mates, conveying different information about male fitness in each one (Simmons et al. 2013).

Similarly, some katydids use air-borne sounds and substrate vibrations during courtship to improve the localization of a stridulating male (Kalmring et al. 1997). In some chorusing insects, like those in the family Gryllotalpidae, the vibrational component of the male advertisement call determines how far apart calling males are from each other in the wild (Hill and Shadley 2001). Male *Drosophila* also use vibrational tapping and chemical aphrodisiacs to attract mates (Butlin et al. 2011).

## Conclusion

The world around us is full of insect signals – the electric iridescence of the emerald green ash borer, the soothing song of a serenading cricket, the marching ants directing each other with chemicals, and the vibrational duetting of tree-hoppers. Insects have evolved incredible means of communicating in many contexts. In addition to representing the spectacular diversity of signal evolution, the study of insect communication has many implications for the overall study of animal behavior. Like most animals, insects can communicate information about identity, status, future actions, environmental discoveries, etc. to multiple receivers (Bradbury and Vehrencamp 1998). Studying how such signals evolve across insect taxa can help elucidate general evolutionary principles. The many modalities that insects use to communicate also inform the creation of human biomimetic devices. For example, the incredible sound localizing abilities of the tachinid fly *Ormia ochracea* prompted the development of a new line of hearing aids (Kuntzman and Hall 2014). Studying insect communication also has various practical implications. The field of forensic entomology relies on understanding how insect localize and communicate resources to glean important information at crime scenes. Studying the signals requisite to mate attraction and other biologically relevant function can inform conservation practices for endangered insect species. Lastly, researchers have used mating and resource localization

signals to develop reproductive suppression and biological control plans in pest management.

## Definition

Insect diet refers to the food usually eaten by an insect for growth, tissue maintenance, and reproduction, as well as the energy necessary to maintain these functions.

## Introduction

Most insects have qualitatively similar nutritional requirements in proteins, carbohydrates, lipids, vitamins, minerals, trace elements, and water (Table 1). These chemical compounds can either be synthesized by the insects themselves, provided by beneficial symbionts or acquired in food (Chapman 2012). Insect diets, and thus the fraction of nutrients acquired in food, can considerably vary among species and developmental stages of the same species, resulting from adaptations to particular environments in which access to nutrients is restricted by the types and diversity of foods available. Herbivores, which make up the majority of insects, eat plants and are typically trophic specialists, which means that they consume only one or a few plant species. By contrast, entomophagous, carnivorous, zoophagous, detritivorous, xylophagous, graminivorous, and omnivorous insects tend to be more generalists.

While the domestication of insects started somewhere around 5000 years ago, with the cultivation of silkworms and honey bees, research on insect nutrition only developed at the beginning of the twentieth century. Key discoveries were made

possible through the multiplication of attempts for designing artificial diets, whose composition can be only partly (meridic diet) or fully (holidic diet) defined. In 1908, Bogdanov was the first to rear an insect (blowflies) entirely on an artificial diet made of peptone, meat extract, starch, and minerals. Since then, famous entomologists, such as Painter, Fraenkel, Dadd, Waldbauer, Dethier, Scriber, and Slansky and Bernays and Chapman, among others, have developed methods and concepts that set a revolution for research on animal nutrition (for a brief thematic history, see (Raubenheimer et al. 2009)). These experiments demonstrate that insects actively attempt to achieve of nutritional balance by carefully regulating their intake of several nutrients simultaneously either from artificial diets or natural foods. Beyond advancing fundamental knowledge on insect nutrition, this research also provided a framework for a series of pioneering nutritional ecology studies that helped establish major concepts of biology and ecology, such as, for instance, ecological niches.

## Nutrients

Foods are complex mixtures of nutritional and non-nutritional (sometimes toxic) compounds. For insects, these compounds typically involve

macronutrients (proteins, carbohydrates, and lipids), micronutrients (vitamins and minerals), and water, which all directly participate to physiological functions (Cohen 2015). Some of these nutrients are essential, which means that insects lack the ability to synthesize them on their own and must acquire them in food or from beneficial symbionts (Table 1). Others, such as food additives (stabilizers, preservatives, bulking agents) and token stimuli (plant secondary compounds) have no direct nutritional function.

## Proteins

Proteins are made of amino acids (organic compounds containing an amino (-NH<sub>2</sub>), carboxyl (-COOH) groups, and a specific chain) and are the principal source of nitrogen for insects. While free amino acids can be present in foods, most often they are linked together by peptide bounds to form proteins. Once assimilated, proteins are broken down into their amino acid components and turned into different proteins that can be used for a wide range of biological functions, such as cell structure, enzymes, transport and storage, or receptor molecules. Insects require nine to ten essential amino acids (Table 1). The others, non-essential, amino acids are generally synthesized in the fat body provided that precursors are available in the food, although other tissues can also be

**Insect Diet, Table 1** Minimal (irreducible) nutrients shown to be useful or essential to insects. Depending on species, some of these nutrients can be nonessential or even toxic (e.g., cellulose). (Modified from (Cohen 2015))

| Proteins              | Lipids                | Carbohydrates   | Vitamins               | Minerals   |
|-----------------------|-----------------------|-----------------|------------------------|------------|
| Polypeptides          | Sterols               | Hexose          | Water-soluble vitamins | Calcium    |
| Glycoprotein          | Cholesterols          | Glucose         | Ascorbic acid          | Chlorine   |
| Lipoprotein           | β-Sitosterol          | Fructose        | Thiamine               | Copper     |
| Essential amino acids | Stigmasterol          | Disaccharides   | Riboflavin             | Iron       |
| Arginine              | Campesterol           | Sucrose         | Pyridoxine             | Magnesium  |
| Histidine             | 24-methyl-cholesterol | Polysaccharides | Nicotinic acid         | Manganese  |
| Isoleucine            | Phospholipids         | Starch          | Pantothenic acid       | Phosphorus |
| Leucine               | Fatty acids           | Glycogen        | Biotin                 | Potassium  |
| Lysine                | Linoleic acid         | Cellulose       | Folic acid             | Sodium     |
| Methionine            | Linolenic acid        |                 | Choline                | Sulfur     |
| Phenylalanine         |                       |                 | Cyanocobalamin         | Zinc       |
| Threonine             |                       |                 | Inositol               |            |
| Tryptophan            |                       |                 | Lipid-soluble vitamins |            |
| Valine                |                       |                 | Tocopherol             |            |
|                       |                       |                 | Vitamin A              |            |

important (e.g., proline and glutamine are synthesized in the mosquito midgut). Most proteins contain approximately half essential and half non-essential amino acids.

### Lipids

Lipids consist of fatty acids, phospholipids, and sterols. Lipids are an important source of energy, essential components of cell membranes, nutrient transporters, and defensive compounds, serve as pheromones, and are involved in hormone synthesis (e.g., sterols are involved in ecdysteroid or molting hormones and fatty acids in juvenile hormone). Insects can synthesize most fatty acids and phospholipids. However, to do so, polyunsaturated fatty acids are required in the diet. Sterols can serve for energy and the production of hormones and carbohydrates. The major essential sterol, the cholesterol, is abundant in animal tissues but only present in low quantities (if not present at all) in plants and fungal food. Therefore, most phytophagous insects must synthesize cholesterol via dealkylation of plant sterols (e.g.,  $\beta$ -sitosterol and campesterol) (Behmer and Nes 2003).

### Carbohydrates

Carbohydrates include simple sugars (e.g., the monosaccharides sucrose, fructose, glucose, maltose), starch, and other polysaccharides (e.g., cellulose). They serve as respiratory fuel, provide the carbon basis in molecular synthesis, and constitute building materials for the insect cuticle (e.g., polysaccharide chitin). Insects can synthesize glucose by gluconeogenesis from lipids or amino acids (Miyamoto and Amrein 2017) in such a way that some species can live without any sugar intake at all (e.g., wax moth and screw-worm). By contrast, other insects require considerable amounts of carbohydrates in their diet (e.g., honey bee or locust). Not all sugars are usable by all insects (e.g., melibiose is digested by many flies but not by honey bees), and some monosaccharides can be toxic because they compete with other essential sugars (e.g., mannose blocks glucose pathway in bees). The digestive capability for carbohydrates also varies among insect species. For instance, flour beetles can hydrolyze a

broad range of polysaccharides, whereas the grasshopper *Melanoplus* only accepts simple sugars. Digestibility of carbohydrates also varies between developmental stages of the same species (e.g., mosquito larvae use starch and glycogen while adults cannot). Cellulose cannot be digested by most insects and thus has no nutritional value.

### Vitamins

Vitamins are organic compounds required in trace amounts for growth. Vitamins are classified in two groups depending on their solubility in water or lipid. Water-soluble vitamins have a relatively short half-life (excreted and lost from the insect's metabolic pool), while lipid-soluble vitamins remain compartmentalized in lipid stores. The main water-soluble vitamins include vitamin C (ascorbic acid) and the B vitamins. Vitamin C serves as phagostimulant and antioxidant and promotes the synthesis of collagen and the extracellular matrix in insects. The B vitamins are involved in many metabolic pathways, including ATP production (thiamine, riboflavin, niacin), acyl group transfer (pantothenate), and growth factor (biotin and folic acids). Some insects also require small quantities of other water-soluble vitamins such as choline (for the production of cell membrane), carnitine (for lipid metabolism), cyanocobalamin, and lipoic acid. Lipid-soluble vitamins essential to insects are the vitamin A complex ( $\beta$ -carotene and related carotenoids relatives) and vitamin E (tocopherols). Vitamin A is required for visual pigments function and formation. Vitamin E serves as fertility factor, including spermatogenesis and egg maturation.

### Minerals

Calcium, chloride, copper, iron, magnesium, manganese, phosphorus, potassium, sodium, and zinc are vital in small quantities to many insects. These compounds are involved in the synthesis of coenzymes and metalloenzymes. Potassium, chloride, calcium, and sodium are essential for the excitability of tissues (e.g., muscle cell and neurons). Potassium and magnesium are major actors of the bioenergetics activity, respectively, via the ATP and glycolysis pathway. Pollutant minerals, present in the environment and passively ingested

by insects, can replace dietary minerals and act as toxins.

### Water

Water is essential to all insects. It provides the medium in which all metabolic processes proceed. As such it is necessary for the absorption of macronutrients. Water often contains naturally occurring micronutrients such as mineral salts. Insects actively ingest free water, have physiological mechanisms controlling thirst, and suffer fitness consequences if water is excessive or deficient in the diet. Meal size and inter-meal duration are both influenced by free water availability.

## Consequences of Diet on Behavior and Physiology

Insects have evolved behavioral and physiological strategies to acquire appropriate amounts and balances of the required nutrients from complex food mixtures. In most environments, no single food provides an optimally balanced diet for the insects. In such case, individuals must adjust their dietary choices and nutrient assimilation rates to reach and maintain a balanced diet (Simpson and Raubenheimer 2012).

### Studying Nutrient Regulation: Nutritional Geometry

The study of nutrient regulation by insects took a significant step forward at the end of the twentieth century when Raubenheimer and Simpson (1993) introduced a unifying theoretical framework for nutrition studies known as “nutritional geometry.” This framework employs a state-space modeling approach taking into account the multiple interactions among mechanisms regulating the intake of different classes of nutrients. Individual insects, foods, and their interactions are represented graphically in a geometric space (a nutrient space) defined by two or more food components, typically carbohydrates and proteins (see examples Fig. 1). Foods are radials through the nutrient space at angles determined by the balance of nutrients they contain (nutritional rails). The insect’s state (nutritional state) is a

point or region that changes over time. As the insect eats, its nutritional state changes along the rail for the chosen food. The functional aim for the insect is to eat foods in appropriate amounts and ratio to direct it to an optimal nutritional state (intake target). This intake target moves over time as the quantity and mix of nutrients change with activity, growth, development, reproduction, and senescence. For instance, in larval insects, early stages typically have diets richer in nitrogen than later stages. The intake target also shifts over evolutionary times as insects adapt to different diets. Insects that feed on other animals have high amino acid and fat requirements relative to carbohydrates, reflecting the relatively high protein and low carbohydrate content of animal tissues. Plant-feeding insects, however, generally require approximately equal amounts of amino acids and carbohydrates. Over the past decades, nutritional geometry has proved a powerful tool to understand how insects and other animals balance their diet across a wide diversity of taxa, feeding guilds and ecological of environments both behaviorally and physiologically (for a recent review, see (Raubenheimer and Simpson 2018)).

### Behavioral Regulation

An insect can respond to a dietary imbalance in one of three ways. First, it can move from eating one food to another with a different nutrient balance. Hence, when given a choice between complementary foods (foods defining a nutrient space containing the intake target of the animal), most insects have been shown to self-compose a nutritionally balanced diet (Fig. 1a). This is possible because insects have separate appetites for different nutrients. Grasshoppers, caterpillars, aphids, flies, and cockroaches regulate their intake of protein and carbohydrates to a single intake target. Predatory ground beetles (Carabidae) have separate protein and lipid appetites. In locusts, levels of water are also regulated together with protein and carbohydrates (Clissold et al. 2014). This ability to adjust food intake to nutritional requirements implies some feedback of nutritional status on food selection and feeding behavior. In locusts, blood-borne nutrient feedback from eating a diet rich in amino acids depresses the sensitivity of peripheral contact

**Insect Diet, Fig. 1** Examples of nutritional geometry models for hypothetical insects. (Modified from (Lihoreau et al. 2018)). (a) Nutritional rails (gray lines) represent the ratio of nutrients X and Y in foods. The blue dot is the nutritional state (NS) of the individual, and the red dot is its intake target (IT). Foods 1 and 2 are individually imbalanced but complementary (fall on opposite sides of the IT). The individual can reach its IT by combining its intake from the two foods (arrows). (b) The

individual is restricted to a single imbalanced food and can (1) satisfy its needs for Y but suffer a shortfall of X; (2) satisfy its needs for X but over-ingest Y; and (3) suffer a moderate shortage of X and excess of Y. (c) Nutritional performance landscapes showing the effects of nutrients X and Y on fitness traits 1 and 2. In this example, trait 1 is maximized for a high X to Y ratio, whereas trait 2 is maximized for a low X to Y ratio

chemoreceptors to amino acids in the diet but has no effect on the sensitivity of chemoreceptors to sucrose. Conversely, if the insect feeds on a diet with high levels of carbohydrates, the sensitivity of its receptors to sucrose is depressed. In species that heavily rely on learning and memory for foraging, such as bees, cognitive capacities are crucial for nutrient balancing by enabling insets to associate the quality of the food with feedback on their own nutrient status based on the visual, olfactory, and tactile characteristics of foods. In drosophila,

protein appetite in mated females results of a sex peptide that is introduced with male's seminal fluid during mating, which stimulates special sensory neurons in the female's reproductive tract. An additional mechanism responding to the protein demands of egg development then controls how much yeast is eaten, involving TOR/S6 kinase and serotonin signaling pathways in the central nervous system (Vargas et al. 2010).

Second, insects feeding on imbalanced foods can also adjust the total amount ingested to

acquire enough of the most limiting nutrients. Grasshoppers, caterpillars, cockroaches, aphids, and ants have been shown to increase the amount eaten if the entire nutrient composition of a diet is diluted with some inert non-nutritional substance. Insects can also selectively compensate for deficiencies in a class of nutrients by increasing the total amount eaten. When confined to a single, nutritionally imbalanced food (that does not allow the intake target to be reached), insects can compromise between overconsuming excess nutrients and eating too little of the nutrients in deficit. The form of this compromise in a nutrient space varies according to the nutrients involved and the ecology of species (Fig. 1b). For instance, when forced to ingest diets containing an unbalanced ratio of proteins and carbohydrates, specialist migratory locusts (*Locusta migratoria*) do not substantially overconsume the excess nutrient to decrease its deficit of the other nutrient. In contrast, in the generalist desert locust (*Schistocerca gregaria*), individuals ingest a greater amount of either protein or carbohydrate to gain more of the more limiting nutrient. This pattern of host-plant generalists being more willing to tolerate nutrient excesses than host plant specialists is widespread across grasshoppers and caterpillars and is accompanied by a greater tendency by generalists to store excesses in body reserves (Behmer 2009).

### Physiological Regulation

A third mechanism to face food nutritional imbalance is to adjust the efficiency with which the insect uses the ingested nutrients. The importance of such post-ingestive regulation has been best studied in locusts. These insects maintain a relatively constant increase in body nitrogen despite a threefold increase in the amount of nitrogen ingested. Most of the excess of protein is excreted as uric acid or some other unknown nitrogenous end product of catabolism. Other means of post-ingestive regulation include differential secretion of digestive enzymes to lower the efficiency of digestion excess carbohydrate or protein in the diet, the adjustment of the timing of gut emptying to alter the ratio of protein and carbohydrate absorbed from the gut, the increase of metabolic

rate to burn off excess ingested carbohydrate, or the selection of environmental temperatures that favor the utilization of either proteins or carbohydrates.

### Consequences of Diet on Fitness

Although some growth occurs on foods containing widely differing levels of nutrients, optimal performance requires the nutrient levels to be appropriately balanced. Ingesting and processing excessive quantities of food in order to obtain enough of a particular component that is present only in low concentration in the diet can prove costly in various ways. Firstly, some nutrient excess can be toxic or have deleterious effects (e.g., excess of carbohydrates can result in obesity-like syndromes in many insects). Secondly, interconversions from one compound to another can be metabolically costly and the rates at which they occur limited. These effects can affect a wide range of fitness traits such as growth, development, reproduction, immune responses, cognition, and life span. The interacting effects of nutrients on fitness traits are evident when mapping insect performances into nutrient spaces of nutritional geometry (Fig. 1c). Different traits often have different nutritional optima, which means that insects must make feeding decisions to trade-off between optimizing multiple traits simultaneously. The ability of insects to resolve these nutritional trade-offs has been first demonstrated in the fruit fly *Drosophila melanogaster* (Lee et al. 2008). When confined to 1 of 28 artificial diets varying in protein and carbohydrate content, female flies achieve a maximum life span on a diet containing a 1:16 ratio of protein to carbohydrate, while maximum egg laying rate is reached on a 1:2 protein to carbohydrate ratio. When allowed to self-select complementary foods, flies mix a diet comprising a 1:4 protein to carbohydrate ratio which maximizes lifetime egg production, a measure of global fitness. Similar trade-offs have been observed in many other insect species for life span and reproduction, immunity and reproduction, or even traits related to different stages of reproduction that cannot be attained simultaneously.

## Consequences of Diet on Biotic Interactions

Upon its influence on the physiology, behavior, and fitness of individual insects, the diet can affect social behaviors and interspecific interactions (e.g., with symbionts, competitors, predators) and ultimately influence species assemblages and communities.

### Social Behavior

In gregarious and social insects, diet influences collective behaviors and social structures (Lihoreau et al. 2018). At the most basic level, a deficit in key nutrients in the environment can generate mass movements. In the Mormon cricket, *Anabrus* the lack of proteins and mineral salts due to intense competition and food depletion during population outbreaks triggers intense cannibalistic interactions. By attempting to eat each other, crickets engage in mass migrations, whereby millions of individuals form marching bands extending over several kilometers (Simpson et al. 2006). In social caterpillars that forage in trails, differences in the nutritional states among trail members determine the identity of leaders (hungry) that guide the group and followers (well-fed) that follow behind. In more integrated insect societies, differences in early food experience can also mediate reproductive division of labor. This is the case in cooperative breeding burying beetles that feed on shared carcasses, where dominant females that access food in priority ingest more proteins and become breeders, whereas subordinate individuals that acquire relatively less proteins become sterile helpers. In eusocial insects, such as honey bees, differential nutrition of the larvae influences caste determination, so that female larvae fed a diet rich in royal jelly become reproductive queens, whereas female larvae fed lower levels of jelly become sterile workers.

### Ecological Interactions

#### Symbionts

An estimated 10% of all insects utilize diets that are nutritionally so poor or unbalanced that they

depend on beneficial symbiotic organisms for sustained growth and reproduction. These associations provide them with metabolic capabilities or additional nutrients (e.g., essential amino acids in insects feeding on plant sap, vitamins in insects feeding on blood, and sterols in insects utilizing wood). In some insects, resident microorganisms degrade complex dietary components to a form that can be assimilated by the insect. This is the case of termites that rely on a rich gut microbiota community to degrade cellulose or soil matter (Bignell et al. 2010). In plant-sap feeding hemipterans that eat phloem and xylem low in essential amino acids, the microorganisms have a biosynthetic function. In *Drosophila*, where gut symbionts are acquired from the environment, variations in microbe communities can trigger different foraging strategies in the hosts that need to compensate for different nutrients (Wong et al. 2017). Other insect species have evolved ectosymbiotic associations. This is the case of fungus-farming termites and leaf-cutter ants that cultivate their own crop in well-protected gardens. In these social insects, foragers collect plant materials not digestible by the insects to feed a fungus that provides accessible key nutrients to the insects. In ants, workers regulate food intake to nourish the fungus with nutrient balances that maximize the production of edibles for the colony, at the expense of fungus reproduction (Shik et al. 2016).

#### Parasites and Pathogens

The diet can also affect the immunological responses of insects and their interactions with parasites and pathogens. For instance, caterpillars of the African cotton leafworm (*Spodoptera littoralis*) infected with either a bacterial or viral pathogen survive better as the ratio of protein to carbohydrate in the diet is increased despite the toxic effect of protein on life span. By contrast, uninfected larvae perform best on an intermediate nutrient ratio. When given a choice between multiple artificial diets, infected caterpillars tend to increase their consumption of protein, which has the consequence of enhancing the immune response, a nutritional behavior akin to self-medication (Lee et al. 2006).

### Dietary Breath and Niche Partitioning

At a broader observation scale, variation in insect diet can determine the coexistence of species and shape local development of biodiversity. For instance, closely related species of generalist-feeding herbivores (grasshopper species in the genus *Melanoplus*) eat protein and carbohydrates in different absolute amounts and ratios even if they eat the same plant taxa (Behmer and Joern 2008). The existence of species-specific nutritional niches, such as this one, provides a cryptic mechanism that helps explain how generalist herbivores with broadly overlapping diets coexist.

### Conclusions

There is a long history of developing artificial diets to culture insects for the food industry and academic research. This approach has showed that most insects have qualitatively similar requirements for macro- and micronutrients as other animals. Over the past decades, new concepts of nutritional ecology have moved the focus from the identification of essential and nonessential nutrients in insect diet to the study of interactions between food components and their consequences on fitness. Insects have evolved sophisticated behavioral and physiological strategies to reach and maintain nutrient balances and concentrations maximizing multiple fitness traits, and this is flexible throughout development. These consequences of diet can be observed at the individual level and beyond, across levels of biological organization. Integrative approaches of modern insect nutrition research offer a means for addressing more general problems in ecology, including the structuring of food webs, the regulation of food chain length, the flow of nutrients through ecosystems, and the dynamics of communities and ecosystems (Simpson et al. 2015).

high reproductive capacity. At the broadest level, they are organized to produce the greatest number of successful, mature offspring. Almost all of them are born from eggs, with larvae and adults encased in an exoskeleton which is periodically shed to allow for an increase in body size.

Although some common groups can live for two or more years, most of them live for a short period of time. Some insects in the temperate region adopt strategies to remain active during the winter, while others migrate to a warmer climate or enter a state of torpor. There are species in which the number of generations is constant, with few occurrences during the year, and others that can complete their life cycle in a few weeks, with many generations per year.

These are just some of the ways in which insects adapt to life in the world around us. In this chapter, we point out the main patterns in the life history of insects, including interesting and often unique characteristics of types of reproduction, mating behavior, reproductive system, egg structure, embryogenesis, growth, and development.

## Introduction

Insects are one of the most abundant and diverse groups of animals on Earth, inhabiting almost every conceivable terrestrial and freshwater environment and, less commonly, the marine habitat. Their morphological diversity and characteristics of life history are highly adaptable to live in various conditions, including extremes of heat and cold, wet and dry, and unpredictable climates. The success of the Insecta is largely related to their

## Types of Reproduction

The usual reproductive mode of insects is sexual reproduction. It consists in the fusion of male and female gametes to form the zygote. Except for Apterygota, where males deposit the spermatophore on the substrate for females to collect, the common way for insects to copulate is to transfer sperm directly to the female during copulation. In general, copulation occurs when the male introduces its copulatory organ into the female genital capsule. Less commonly, male use the aedeagus to pierce the abdomen of the female and inject sperm into the abdominal cavity. This unusual mode of copulation, known as traumatic insemination, occurs in fruit flies (Diptera), Stylopodia (Strepsiptera), and it is prevalent and best investigated in bed bugs (Cimicidae, Hemiptera) (Peinert et al. 2016).

Many insects reproduce asexually. The phenomenon of parthenogenesis, in which eggs do not need to be fertilized to develop embryos, is present in several groups. Parthenogenesis can be mandatory, but not as common as sexually

reproducing, or facultative. The latter may occur as a response to fluctuations in environmental conditions, or even when females fail to find a mate. An unfertilized egg can generate only female individuals (thelytokous parthenogenesis, e.g., aphids), only male individuals (arrhenotokous parthenogenesis, e.g., bees and ants), or individuals of both sexes (deuterotoky parthenogenesis, e.g., cynipid wasps and micro-malthid beetles).

Another way of asexual reproduction in insects is the polyembryony; it occurs when a single egg undergoes fission giving rise to two or more embryos. This sort of reproduction is restricted predominantly to Hymenoptera and few Strepsiptera, and seems to have evolved independently among different groups of animals. In the parasitic wasps, the number of embryos produced can be influenced by the size of the host, varying from 10 to several hundred embryos arising from one egg. Characteristically, the eggs of polyembryonic species are devoid of yolk, and its nutrition is acquired from the host's hemolymph through a specialized enveloping membrane called the trophamnion, a modification of the serosa layer (see [Embryogenesis](#) section).

## Mating Behavior

### Mate Location and Recognition

The reproductive success of the insect species depends on the synchronicity of gonadal maturation and the location of the mating place. It can be facilitated by several species-specific signals produced by each individual to find and attract a sexual partner of the same species. These signals can be visual, like the flashing lights of fireflies; acoustic, such as the song of cicadas and crickets; or chemical, where individuals release olfactory substances (sex pheromones) to be recognized by the opposite sex.

Another fundamental behavior of insects for bringing the sexes together is swarming. It is observed in several groups of insects such as dragonflies, mayflies, butterflies, and many dipterans. The individuals in the swarm are usually all males, although swarms of females also occur

in some species. The process of swarm formation is more evident when many individuals are involved, but a single male insect taking over a spot is also possible. In both cases, females use visual cues to identify the site. During group swarming, males commonly do not perform intrasexual aggression in the absence of females, and when they arrive, females are immediately grabbed and the copulation takes place without courtship. In some groups, such as drosophilid and tethritid fruit flies, aggressive males form substrate-based aggregations in order to defend a territory against conspecific males and court of arriving females.

### Courtship

Courtships rituals are intraspecific and intersexual behaviors that stimulate the receptivity of a potential partner before mating, especially in species where females are normally aggressive. These rituals have great influence on the choice of a partner by the female, being an important role in sexual selection. In general, the courtship includes visual displays of adorned parts of the body and specific movements, including sound production. Male of some drosophilid fruit flies, per example, vibrate their wings producing a sound that has a function both as a sexual stimulant and in sexual isolation (Costa and Sene 2002). In many groups of insects, tactile stimulation using the antennae, palps, and legs occurs with the proximity of individuals before mating, and may continue during copulation. An interesting example of courtship can be seen in the hanging flies (Bittacidae) and dagger flies (Empididae), where males offer to the females a prey as a nuptial gift to be consumed during copulation. If the courtship is successful, and the movements are performed correctly, mating occurs (Vahed 2007).

## Reproductive System: Male

### Internal Reproductive Organs

The reproductive system of male insects is typically formed by paired testes, vas deferens and vas efferens, seminal vesicle, a median ejaculatory duct, and several accessory glands (Fig. 1). The

**Insect Life History,**

**Fig. 1** Schematic drawing of an internal reproductive organ of a male insect showing its basic parts

paired testes may be located above or below the gut, connected or not with each other. They are responsible for the spermatozoa production after successive stages of maturation within a series of sperm tubes. While in some lepidopterans the testes can be fused to form a single structure, more primitive insects may have only a single testis. Individual vas efferens connect the sperm tubes to the vas deferens of each testis. The transport of sperm from the testes is made by peristaltic contractions of the muscular wall of the vas deferens which leads the sperm to the seminal vesicles. This structure is an enlarged area of the vas deferens and is frequently glandular, which may indicate a possible nutritive function. The terminal portion of the vas deferens is connected to the anterior tip of the ejaculatory duct, that is composed by a cuticular lining with walls entirely sclerotized. Posteriorly, the ejaculatory duct may run through an evagination of the body wall, which thus forms an intromittent organ, the aedeagus. In insects that form a complex spermatophore, subdivision of the ejaculatory duct into specialized regions may occur. The accessory glands may be attached with the vas deferens or the ejaculatory duct. They consist of a single layer

of cells that may be coated with a muscular tissue, and their number and forms are variable among insects. Male accessory glands become active and increase greatly in size as a result of the synthesis and accumulation of materials used in spermatophore and/or seminal fluid. They are also responsible for producing substances that affect the behavior and physiology of the female. During insemination, peptides produced by the accessory glands are frequently involved in triggering her reproductive processes, including oogenesis and oviposition, or terminating subsequent female mating behavior to prevent her from acquiring the sperm of another male. Since insects have a diversity of mating systems, the specific functions of accessory gland secretions are likely to reflect this variation.

### Sperm Production

The sperm tubes, or testicular follicles, are bound together by connective tissue or peritoneal sheath each one containing the gametes development areas. The follicle number varies considerably, with only 1 follicle in some coleopterans up to more than 100 in certain orthopterans. Within each follicle, several zones of development can

be readily distinguished. At the anterior portion is the germarium in which spermatogonia are produced from germ cells. As the spermatogonium moves posteriorly into the zone of growth, each one becomes enclosed by a layer of somatic cells to form cysts. Within the cysts, each spermatogonium undergoes mitotic divisions and then moves down to the zone of maturation. In this portion, the spermatocytes become haploid spermatids after multiple meiotic divisions and complete a developmental transformation into flagellated spermatozoa. At this point, the cyst wall breaks and the spermatozoa migrate to the seminal vesicles where they remain as a reservoir of sperm until the insect copulates with a female.

### Transfer of Sperm to the Female

The sperm and the seminal fluid are transferred from male to female during copulation into a process known as insemination. It may occur in distinct ways (indirect or direct insemination) and depends on a variety of circumstances such as male investment, female selection of mates, sperm competition, and structure of genitalia. In some cases, spermatophore (sperm packet) is produced by the male before copulation or, more often, as copulation proceeds. In the most primitive insects, the male deposits a spermatophore onto the substrate for the female to take it up to the reproductive tract; in springtails it occurs quite independently of the presence of a female, which preferably selects spermatophores of males that were exposed to a competitor (Zizzari et al. 2013). In more advanced insects, the sperm are transferred directly in seminal fluid and the spermatophore is no longer produced. In such instances, copulation involves the physical apposition of male and female genitalia and the transfer of seminal fluid via the insertion of part of the aedeagus into the reproductive tract of the female. The aedeagus is thin-walled and erected by hydrostatic pressure, either of the hemolymph or fluid contained within a special reservoir of the ejaculatory duct. It extends far into the genital tract of the female and ends adjacent to the spermatheca. Alternatively, the aedeagus may be rigid and erection achieved using muscles, penetrating only a short distance into the female's genital tract.

## Reproductive System: Female

### Internal Reproductive Organs

The basic components of the female system are paired ovaries connected at their posterior ends by a pair of lateral oviducts that converge to a common oviduct (Fig. 2). Posteriorly, the common oviduct is confluent with the vagina. The ovaries are usually dorsolateral to the gut and are composed of a series of tapering units, called ovarioles. The number of ovarioles varies among species and its particular life history, being from 4 to 10 per ovary in most insects up to 1000 or even more per ovary in queen termites. At the anterior end of each ovary, all ovarioles are united by a suspensory ligament that anchors the ovary to the body wall. The essential parts of the ovarioles consist of a terminal filament, germarium, vitellarium, and pedicel. When fused, the terminal filaments form the suspensory ligament. The pedicel connects each ovariole to a lateral oviduct. This structure is characterized by a thin-occluded tube formed by epithelial tissue, which is lost during ovulation.

The common oviduct can be associated with multiple specialized structures as a spermatheca, genital chamber, bursa copulatrix, fertilization chamber, and accessory glands (Fig. 2). After insemination, the sperm are stored in the spermathecae and then released into the common oviduct through spermathecal ducts. The genital chamber is the result of a modification to the common oviduct capable of incubating eggs internally. Within the chamber is an additional pouch into which sperm are first deposited after mating, the bursa copulatrix. In some species, the bursa forms a diverticulum externally to the oviduct. In nearly all lepidopterans the bursa is physically distinct from the oviduct and opens to the outside via the vulva. A narrow sperm duct connects the bursa with the oviduct and forms the route along which the sperm migrate to the spermatheca where they are stored more permanently. Another additional sperm storage organ present in some acalyptate flies is the fertilization chamber, formed by a cuticular extension of the ventral wall of the bursa copulatrix. The sperm initially stored in the chamber is transferred to the

**Insect Life History,**

**Fig. 2** Schematic drawing of an internal reproductive organ of a female insect showing its basic parts

spermathecae for long-term storage while a smaller number is retained in the chamber for the fertilization of eggs. It is believed that the presence of multiple sperm storage organs is driven by sexual selection making females able to manipulate the ejaculations, in addition, to reduce wastage of sperm prolonging their refractory period (Twig and Yuval 2005). Accessory glands may be present and usually open into the bursa, but in some groups, they are associated with the lateral oviducts. Among a variety of functions, the accessory glands are responsible for the production of substances for sperm maintenance, transport, and fertilization, as well as for the protection of eggs.

### Oogenesis

Within ovarioles, just beneath each terminal filament is the germarium, where the oocytes begin to grow from the oogonia. As oocytes mature, they pass back down the ovariole and are clothed by a follicular epithelium, which is derived from mesodermal prefollicular tissue located at the junction

of the germarium and vitellarium. Oocyte growth continues apace by cell division. In the vitellarium, the yolk is deposited in the oocytes in a process called vitellogenesis. At this stage, follicle cells no longer divide becoming stretched over the oocyte as a flattened squamous epithelium. As yolk accumulation nears its end, the function of the follicle cells changes and they produce the vitelline envelope and the ligands responsible for determination of the terminals of the embryo and its dorsal-ventral axis. In the last stage, they produce the chorion (eggshell).

### Ovulation and Fertilization of the Egg

The passage of an egg from the ovariole into the oviduct is known as ovulation. Muscular contractions of the oviduct walls are coordinated by hormones that are secreted by neurosecretory cells when the central nervous system receives a confirmation that mating has occurred and that eggs are indeed mature. In a first moment, the anterior portion of the spermathecae contracts, sperm are

forced down the spermathecal duct where they are held until sensory cells indicate that the egg has achieved the proper position in the genital chamber. Many female insects store the sperm that they receive from one or more males in their spermatheca. Sometimes, sperm may remain viable in the spermatheca for a considerable time, being maintained by secretions from the female's spermathecal gland; honey bees can store sperm for more than three years (Collins et al. 2006).

Eggs are fertilized as they pass down the median oviduct and vagina. At that point, the sperm enters the egg via one or more micropyles, a modification of the normally impermeable chorion. The micropyle or micropylar area is orientated towards the opening of the spermatheca during egg passage, facilitating sperm entry.

### Oviposition

Once fertilized, the eggs pass from the external genital opening or vulva to the outside of the female body through an ovipositor. This process is controlled by peristaltic waves of muscle contractions. In most insects, the ovipositor consists of two to three pairs of slender valves, the valvulae, arising from basal plates, or valvifers, on the eighth and ninth abdominal segments. The third pair of valves originates from the posterior region of the second valvifers. Accessory glands of the common oviduct may produce cement that allows the deposited eggs to be glued together or attached to the substrate. Alternatively, in some insects, the eggs may be retained for variable periods until the eggs hatch or the larvae mature.

Oviposition is often associated with behaviors such as digging or probing into an egg-laying site. The eggs may be deposited on or near the food required by the offspring upon hatching, but often they are simply dropped to the ground or into water.

## Egg and Embryology

### Egg Structure

Insect eggs are extraordinarily diverse in forms, mostly varying between spherical, oval, elongate,

conical, barrel-, or disk-shaped. The eggshell may also be sculptured with ridges, spines, or other processes, and some are brightly colored. However, their appearance may be affected by factors like adult body size, feeding habits, ecological and life history, and mainly by the ecology of oviposition (Church et al. 2019; Hinton 1946). Shifts to aquatic and internal parasitic oviposition, per example, were significantly associated with the evolution of different structures like respiratory horns in aquatic hemipterans, and smaller eggs in parasitoid wasps, allowing flexibility during passage down the narrow ovipositor.

Insect centrolecithal egg cells (oocytes) have a great amount of lipids and yolk, which serves as the source of nutrients for the development of the embryo. The cytoplasm is distributed in diffuse strands throughout the yolk (reticulum) and in peripheral bounding layer (periplasm). Nucleus usually occupies a posterior position, lying within the yolk. Enclosing all these components is the eggshell protecting the developing embryo from external elements, predators, and parasites.

The innermost layer of the eggshell is the vitelline membrane. It may vary in thickness in distinct insects and in different parts of the egg. In insects that lay eggs in dry places, a wax layer occurs adjacent to the vitelline envelope, assuring resistance to desiccation. Above the wax layer is a complex multilamellar chorion formed by two main layers: a proteinaceous endochorion and an exochorion rich in carbohydrate. The thickness and presence of both layers, however, is variable among many groups. Openings in chorion are restricted, limiting water loss. However, to allow gas exchange between the egg and environment, the chorion is perforated by microscopic pores (aeropyles). During fertilization, sperm entry to the oocyte is facilitated by the tiny openings of the egg called micropyles. Finally, the chorion of some species has a line of weakness along which it splits, allowing the larva to more easily escape during hatching.

Many insects are capable to produce extra egg coverings by secretions of female colleterial glands. Some insect lineages enclose their thin-shelled eggs in protective tanned or foamy outer covering (ootheca), notably orthopterans,

mantids, and cockroaches, or cover the eggs with some sort of protective material, like a proteinaceous secretion or cement.

## Embryogenesis

Embryogenesis begins once the egg has been fertilized. It involves multiplication of cells by mitosis, resulting growth, movement, and differentiation into all the tissues and organs. Due to a large amount of yolk, insect eggs undergo an unusual type of superficial cleavage.

In an earlier moment, there are no cell divisions and only the zygote nucleus divides. The daughter nuclei together with their surrounding cytoplasm (energids) migrate to the egg periphery to form a syncytium (Fig. 3a). After energids settle in the periplasm, nuclear division proceeds followed by subsequent cellularization, resulting in the blastoderm, a single sheet of cells that surrounds the yolk (periblastula stage) (Fig. 3b). Energid cells that drift to the posterior pole of the egg become the germ cells. They migrate later to the developing gonads and turn primary sperm and eggs. Insects with yolkless eggs may have complete

**Insect Life History, Fig. 3** Early stages of insect development. Figures below show cross-section of the eggs immediately above the following: (a) syncytial cleavage; (b) blastoderm and the thickened germ anlage; (c) gastrulation and formation of the gastral groove; (d) germ band after gastrulation, with segment borders and amniotic folds forming (arrows indicate the movement of the serosal cells to enclose the germ band); and (e) advanced germ band stage, with appendage buds, and transient coelomic sacs formed by the mesoderm

cleavage (with complete earlier division of cells), like parasitic wasps, aphids, and springtails.

Blastoderm cells of the ventral region differentiate into the germ anlage, a disc of cuboidal cells that will develop in the future embryo. The remaining blastoderm becomes the extraembryonic membranes (serosa and amnion). The serosa forms the yolk sac and later adjacent cells of germ anlage grow around it, enclosing the embryo in an amniotic cavity bounded by protective amnion membrane (Fig. 3) – serosa and amnion may remain connected or become completely separated. In many holometabolous insects (e.g., lacewings, dipterans, lepidopterans, and hymenopterans) the germ anlage develops from almost the entire blastoderm surface.

Gastrulation begins when the germ anlage thickens and becomes the germ band which corresponds to the ventral portion of the embryo. At this time, the formation of the three germ layers takes place. The mid-ventral cells of the germ band move upward into a space between the embryo and the yolk, thus forming a two-layered embryo with the outermost cells in contact with the amniotic cavity becoming the ectoderm, while cells bordering the yolk resulting the mesoderm (Fig. 3c). At this moment, the dorsal closure occurs, forming the lateral and dorsal parts of the embryo by growth and posteriorly mid-dorsal fusion of the edges of the germ band over the remaining yolk (Fig. 3d). The mesoderm proliferates inward as a longitudinal gastral groove, absorbing the yolk mass and paired coelomic spaces appear (Fig. 3e), while ectoderm ingrowths at the front and rear of the embryo’s body to form the mouth, anus, and fore and hindgut. Endoderm is formed later and results in the future midgut, which establishes contact with the fore and hindgut. It can be formed in three different ways: by the formation of a mid-ventral furrow that subsequently closes over (most orders), by the lateral

overgrowth of a mid-ventral plate (many hymenopterans), or by ingression of individual ventral midline cells (lepidopterans) (Heming 2003).

Segmentation and appendages formation take place nearly simultaneously with the gastrulation (Fig. 3d, e). These processes are controlled by a complex genetic regulatory cascade that specifies the insect body plan along the anterior–posterior axis (Peel et al. 2005). In most orders, the germ band is differentiated into a broad anterior region (protocephalon) and a narrow posterior portion (protocorm) (Fig. 3c).

During the remainder of development, both the mesodermal and ectodermal layers undergo differentiation into tissue-specific cell types and cell rearrangements required to form the final organ structures. Paired coelomic cavities develop as clefts in each segment of the protocorm and in association with the pre-mandibular and antennal segments in the protocephalon. At the same time, the primary body cavity (epineural sinus) develops as a space between the upper surface of the embryo and the yolk. During mesoderm differentiation the coelomic sacs collapse and their lumina fuse with the primary body cavity, thus forming a hemocoel (mixocoel). In Diptera, no coelom cavities are formed (Chapman et al. 2013). In metamorphic insects a cluster of cells invaginates below the ectoderm, forming imaginal discs that do not undergo any differentiation until later larval stages. The fate of germ layers during organogenesis is summarized in Table 1.

Polyembryony occurs in some insect taxa, particularly in parasitic Hymenoptera and few Strepsiptera. In this form of development, the early embryo splits clonally to give rise to two to thousands of embryos. The earlier embryo is referred to as primary morula and later enters the proliferation stage of embryogenesis. It results in the formation of an increasing number of secondary morulae, which consist of nondifferentiated

**Insect Life History, Table 1** Developmental fate of insects’ germ layers in organogenesis

| Germ layers | Organs and structures of adult insects                                                                                                                                  |
|-------------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Ectoderm    | Epidermis, exocrine glands, brain and nervous system, sense organs, fore and hindgut, respiratory tracheal system, Malpighian excretory tubules, and external genitalia |
| Mesoderm    | Heart, blood, circulatory system, endocrine glands, muscles, gonads, and fat body                                                                                       |
| Endoderm    | Midgut                                                                                                                                                                  |

cells surrounded by extraembryonic membranes (Strand 2009).

## Viviparity and Ovoviviparity

In viviparity, the eggs are retained within the parental body after fertilization and the embryos receive nourishment directly from the mother. Due mainly to the lower number of functional ovarioles, viviparous species usually have fewer offspring. Three main types of viviparity frequently occur in different insect groups.

Pseudoplacental viviparity occurs when yolk-deficient or yolkless dechorionated eggs develop within the female genital tract and are nourished by a maternal placenta-like tissue (pseudoplacenta) through which nutrients are transferred to developing embryos. The oocyte is retained in the ovariole, being enclosed by the thickened follicle epithelium that forms a primary maternal pseudoplacenta. Later, it is replaced by an embryonic (fetal) pseudoplacenta formed by serosa and amnion. Nourishment may occur by a communication opening with another extraembryonic cavity (cephalic vesicle), by the ovariole sheath or directly by the serosa membrane, which turns into a trophic organ. Viviparous development continues up to the time of hatching. It is common among many aphids, earwigs, psocids, and polyctenid true bugs.

In adenotrophic viviparity, fully chorionated eggs normally develop in the uterus and larva hatches within it, being nourished by special secretions of maternal accessory milk glands. The larvae remain in the female until mature when they are laid and immediately pupate. A single chorionated oocyte is produced at a time, with another oocyte starting its development just before larviposition. It occurs only in a few blood-sucking dipterans, like tsetse flies (*Glossinidae*) and louse flies (*Hippoboscidae*).

In hemocoelous viviparity fertilization, development occurs in the hemocoel with nutrients taken up by osmosis directly from the hemolymph. Ovaries lack oviducts and larvae emerge from yolkless oocytes and go outside through female genital canals. It is common throughout strepsipterans and gall midges (*Cecidomyiidae*), in the latter case pedogenic larvae feed initially on

parental tissues before escape through a rupture in the female wall.

Ovoviviparous insects provide a safe internal brooding chamber to their developing egg-shelled oocytes but do not supply directly oxygen and nourishment. The embryos are nourished only by the egg yolk. The eggs are retained in genital tract until the offspring are ready to hatch or larvae are deposited just after hatch. Ovoviviparity occurs sporadically or obligatorily in many species of different orders, like mayflies, cockroaches, thrips, aphids and true bugs, moths, a few beetles, and several dipterans (e.g., *Muscidae*, *Sarcophagidae*, and *Tachinidae*).

## Postembryonic Development

### Hatching

The stimuli that give start to the hatching process are mostly unknown and the timing for insects to hatch seems to be intimately close to the development stage. It is known, however, that some factors like temperature, light, and oxygen may influence or even stop hatching from occurring. Insects use a variety of strategies to burst out of their eggs. Most of them simply force their way out by the increase of their body volume (ingestion of extraembryonic fluid and air) and by waves of muscular contraction that bumps the hemolymph to the head and thorax, applying pressure in the interior of the shell. In groups with a thick serosal endocuticle in the egg, hatching is aided by the production of an enzyme that digests this cuticle prior to the hatching process. Some cuticle structures, known as egg busters, also help in the hatching process and are found in a great number of insects, such as dragonflies, grasshoppers and crickets, true bugs, neuropterans, caddisflies, dipterans, beetles, and fleas (Richards and Davies 1997). They may possess many different sizes and shapes, from a central tooth to a pair or a row of spines. Their position in the body also varies, being present in the head, thorax, or abdomen.

The position of the egg rupture usually depends on where the insect puts pressure to hatch. This rupture can occur longitudinally or transversely, and also be guided by one or more

lines of weakness where the chorion splits (hatching line, explained in the [Egg Structure](#) section). After hatching, lepidopteran caterpillars eat the eggshell to their base, and sometimes may even eat the top of the adjacent unhatched eggs. Some insects may possess an embryonic cuticle that is shed during or soon after hatching, in a process called intermediate mould (Chapman et al. 2013).

### Immature Development

Postembryonic development is discontinuous and characterized by a series of stages, separated from each other by a moult and posterior ecdysis. They occur until the insect is an adult and no further (except in Apterygota groups). The moult is controlled by the prothoracicotropic hormone (PTTH), which is produced in the brain and stored at the corpora cardiaca positioned near the aorta wall. The PTTH is latterly released in great amount to initiate each moulting process. The series of stages (usually referred to as instars) mark a period of growth, but usually without a great change in body form. This is only different when the individual moults from the last larval instar to the adult stage. This last change, called metamorphosis, bears a variable amount of modifications usually related to the loss of larval adaptative features and the gain of adult ones, besides the development of the reproductive system. The extent of these modifications is related to the degree of ecological modifications between the last larva instar and the adult.

### Metamorphosis

The difference between the metamorphosis and the initial moulting process is the low level of the juvenile hormone (JH). This hormone, produced by the corpora allata, is responsible for inhibiting the development of adult traces throughout nymphal and larval life during the moulting process. During the last juvenile instar, the corpora allata becomes atrophied and stops producing JH. In adult insects, brain neurosecretions reactivate the corpora allata and JH is secreted again. It is essential in stimulation of the yolk production, spermatophore, and secretions of the accessory glands in males.

Insects can be classified into three categories regarding the changes during metamorphosis: ametabolous, hemimetabolous, and holometabolous. Ametabolous insects bear no differences between adults and juveniles, except that adults stop increasing in size and reach the reproduction maturity. In hemimetabolous groups, the larvae are morphologically similar to the adult, except for the absence of mature reproductive system and wings, and the presence of some larval features such as tracheal gills for aquatic groups. In the holometabolous, however, the larval morphology is completely dissimilar from that of the adult. Between the larval and adult phases, the pupal stadium grants the complete transformation in morphology to the adult form.

Larvae of hemimetabolous basically resemble adults and are commonly referred to as nymphs to distinguish them from the holometabolous, radically different larvae. In nymphs, the wings develop as external pods that become bigger at each moult, finally enlarging during metamorphosis. In holometabolous, the wings develop as invaginations of the epidermis and are only visible when everted during the pupal stadium. The larvae of holometabolous have a huge variety of forms, but they basically fit into three main patterns: the oligopod, with thoracic legs and usually well-developed head capsule and mouthparts; the polypod, which possess abdominal prolegs in addition to the thoracic ones; and the apod, with no legs and poorly sclerotized body. Polypods larvae are found on lepidopteran caterpillars, scorpionflies, some beetles, and hymenopterans sawflies. Oligopod and apod larvae are vastly spread throughout the holometabolous insect orders. An interesting feature, usually common but not restricted to parasite insects, is called hypermetamorphosis. It consists in the presence of two or more types of larvae in the life cycle of the same species and is common throughout microcaddisflies (Hydroptilidae), strepsipterans, and some beetles (Meloidae and Ripiphoridae).

As stated before, the degree of change between the larval and adult phases varies a lot when comparing different insect groups. In hemimetabolous insects, metamorphosis is responsible for the growth of the wing pads into fully formed

wings, besides the development of a membranous basal region and accessory sclerites. The genitalia are progressively developed by the modification of the terminal abdominal segments, but more remarkable changes occur during metamorphosis (Chapman et al. 2013). In holometabolous insects, the development of the adult's features is related to the degree of differentiation between the larvae and adult. In neuropterans and beetles, where the larvae are more similar to the adult, little reconstruction occurs. But in dipterans, per example, the larvae tissues are solved and digested and the adult tissues are almost completely restored (Jindra 2019).

There are two different types of pupae present during holometabolous metamorphosis: the exarate pupa, which has the appendages freely extended from the body, and the obtect pupa, which has the appendages glued to the body. A further differentiation regarding the mandibles is also possible. When articulated mandibles are present in the pupae, the condition is called decticous. The alternative condition, with immobile mandibles, is called adecticous (Hinton 1946). Most insect pupae are immobile and therefore vulnerable, requiring some protection. Many will pupate in a cell, chamber, or cocoon, or will bear protective structures (Gross 1993; Hinton 1946).

### Polymorphism

Polymorphism usually indicates variation in phenotype within a species based on variations in its genome. Polyphenism is the phenomenon where two or more phenotypes are produced by the same genotype and are one of the major reasons for adaptive insects' success. It allows them to partition life-history stages, to adopt different seasonal phenotypes, to cope with temporally heterogeneous environments, and to partition labor within social groups (Simpson et al. 2011).

One of the most interesting cases of polyphenism is the castes in social insects. Among social hymenopterans, for instance, queens and workers are all females. While sex is determined genetically, caste is determined by conditions experienced during larval life. The same occurs between ant workers and soldiers. Aphids also

share a variety of forms, from parthenogenetic females to sexual generations, wingless and winged forms (the latter to disperse to other hosts). All this complexity is guided by environmental factors, like temperature and photoperiod. Besides these examples, many other groups may possess variation in color, form and behavior in response to the habitat conditions.

## Definition

Insects are truly a unique creation of nature. The astonishing success of insects in enduring the changes throughout the course of evolution is marveled by scientists the world over. There are over 900 species of insects reported so far and it has been assumed that there are even more left the discovered yet! The significance of this assumption cannot be stressed enough. It highlights the fact that insects have had a phenomenal success in surviving through the years where most of the other species have struggled. They have thrived in every environment and seem ready to endure even the harshest climatic condition. Insects are found almost all over the world and exhibit various levels of adaptability.

One such adaptability is observed in insect locomotion. Locomotion is an essential component of the insect lifestyle. It helps insect to commute from one place to another. Insects residing in different regions and habitats across the world exhibit different forms of locomotion. These forms include walking, running, crawling jumping, swimming, and flight. Insects are armed by appendages which allows them to move free and without hindrance. The thorax and its associated appendages are primarily responsible for movement in insects. We shall thus delve into the structural details of the locomotary appendages, modifications associated with these appendages, as well as the different types of locomotions found in insects. Insect flight and wing structure has not been included in this chapter as it requires a separated chapter dedicated to itself. The other forms of locomotions have been discussed in details. We shall commence our discussion on insect locomotion by first looking into the structural aspects of insect legs before proceeding to the different mechanisms of locomotion.

## Insect Legs

### General Structure

In most adult and nymphal insects, legs can be segmented into fore, mid, and hind legs. The legs occur on the prothorax, mesothorax, and metathorax, respectively. Each leg can be divided into six segments typically from proximal to distal regions articulating with each other by mono- or di-condylic articulations set in a membrane, the corium.

They are: coxa, trochanter, femur, tibia, tarsus, and pretarsus with claws. Additional segments the prefemur, patella, and basitarsus can also be recognized in some fossil insects and other arthropods, such as arachnids, and one or more of these segments are evident in some Ephemeroptera and Odonata. Primitively, two more segments called the epicoxa, associated with the wing articulation (tergum), and the subcoxa, articulated with the pleuron, were also found. The coxa is often in the form of a truncated cone and articulates basally with the wall of the thorax. There may be only a single articulation with the pleuron in which case movement of the coxa is very free, but frequently there is a second articulation with the trochantin. The part of the coxa bearing the articulations is often strengthened by a ridge indicated externally by the basicostal sulcus which marks off the basal part of the coxa as the basicoxite. The trochanter is a small segment with a dicondylic articulation with the coxa such that it can only move in the vertical plane. In Odonata there are two trochanters and this also appears to be the case in Hymenoptera, but here the apparent second trochanter is, in fact, a part of the femur. The development and size of femur and tibia are intrinsically related to their role in different modes of locomotion, although usually they are considered to be the longest leg segments. For example, walking (grasshopper) and running (cursorial) insects usually have well-developed femora and tibiae on all legs, whereas jumping (saltatorial) insects such as grasshoppers have disproportionately developed hind femora and tibiae. In aquatic beetles (Coleoptera) and bugs (Hemiptera), the tibiae and/or tarsi of one or more pairs of legs usually are modified for swimming (natatorial) with fringes of long, slender

hairs. Many ground-dwelling insects, such as mole crickets (Orthoptera: Gryllotalpidae), nymphal cicadas (Hemiptera: Cicadidae), and scarab beetles (Scarabaeidae), have the tibiae of the fore legs enlarged and modified for digging (fossorial), whereas the fore legs of some predatory insects, such as mantispid lacewings (Neuroptera) and mantids (Mantodea), are specialized for seizing prey (raptorial).

The tarsus is subdivided into five or fewer components, called tarsomeres. This is so called as there is only one tarsal muscle, giving the impression of a segment, but in reality it is only a single segment. Hence, it is also referred to as a pseudosegment. The first tarsomere sometimes is called the basitarsus. The underside of the tarsomeres may have ventral pads, pulvilli, or euplantulae, which assist in adhesion to surfaces. The surface of each pad is either setose or smooth. The pretarsus, which lies at the distal end, bears a pair of lateral claws (also called ungues) and usually a median lobe, the arolium which may be membranous or partly sclerotized. Dipterans possess a central spine-like or pad-like structure empodium (plural: empodia) and a pair of lateral pulvilli. It is because of these structures that flies are allowed to walk on walls and ceilings. The pretarsus of Hemiptera may bear a variety of structures, some of which appear to be pulvilli, whereas others have been called empodia or arolia, but the homologies are uncertain. In some beetles, such as Coccinellidae, Chrysomelidae, and Curculionidae, the ventral surface of some tarsomeres is clothed with adhesive setae that facilitate climbing. The tibia and basal tarsomere of each hind leg of honey bees are modified for the collection and carriage of pollen (Fig. 1).

Although the thoracic legs have been observed in every adult insect form, the abdominal legs are more or less confined to the larval stages of the insect. The term proleg is used for the larval leg. Prolegs on the abdomen, especially on caterpillars, usually are lobelike and each bears an apical circle or band of small sclerotized hooks, or crochets. The thoracic prolegs may possess the same number of segments as the adult leg, but the number is more often reduced, apparently through fusion. In other cases, the thoracic prolegs, like

**Insect Locomotion, Fig. 1** Leg and articulations. Points of articulation shown by bold arrows (mainly after Snodgrass 1935, 1952). (a) Typical insect leg. (b) Dicondylic articulation of trochanter with coxa and the apodemes of muscles moving the trochanter. Notice that

the femur is united with the trochanter; there is no moving joint. (c), (d) dicondylic articulation of tibia and femur, (c) side view, (d) end view. (e) Monocondylic, ball articulation of tarsus with tibia. (Illustration taken from *Insects: Structure and Function*, R.F. Chapman; 4th edition)

those of the abdomen, are unsegmented out-growths of the body wall, often bearing apical hooks (Fig. 2).

## Muscles

The muscles of insect legs can be classified into two main categories based on their location. The

intrinsic muscle which lies inside the legs and extrinsic muscles which lie outside the legs. The intrinsic muscles ran wholly from one segment to the other. The extrinsic muscles have a wide range of roles that it conducts. The movement of coxa is seen to be regulated by the extrinsic muscles attached to the thorax. This is illustrated by the promotor and remotor muscles arising on the tergum, abductor and adductor muscles from the

**Insect Locomotion, Fig. 2** Pretarsus. (a) Pretarsus of *Periplaneta*, ventral view (after Snodgrass 1935). (b) Pretarsus of a dipteran, ventral view (after Snodgrass 1935). (c) Distal part of prothoracic leg of larval *Triaenodes*

(Trichoptera) showing a simple pretarsal segment (after Tindall 1964). (Illustration taken from *Insects: Structure and Function*, R.F. Chapman; 4th edition)

pleuron and sternum, and rotator muscles also from the sternum. The roles of various muscles vary in part due to its nature of articulation as well as roles of other muscles. For example, In *Apis* (Hymenoptera), which has rigid pleural and sternal articulations, promotor and remotor muscles from the tergum are absent. In the pterothoracic segments (thoracic segments related to the attachment of wings), muscles run from the coxae to the basalar and subalar sclerites. They are concerned with movements of the wings as well as the legs.

The intrinsic musculature includes of pairs of antagonistic muscles in each segment. In *Periplaneta*, there are three levator muscles of the trochanter arising in the coxa and three depressor muscles, two again with origins in the coxa and a third arising on the pleural ridge and the tergum. The attachment of femur to the trochanter is such that it is usually immovable, but the tibia is moved by extensor and flexor muscles arising in the femur

and inserted into apodemes from the membrane at the base of the tibia. Levator and depressor muscles of the tarsus arise in the tibia and are inserted into the proximal end of the basitarsus, but there are no muscles within the tarsus moving the tarsomeres. The pretarsus has a depressor muscle but no levator muscle. Levation of the pretarsus results from the elasticity of its basal parts.

Insects have only striated muscles, so-called because of overlapping thicker myosin and thinner actin filaments giving a microscopic appearance of cross-banding. The typical striated muscle fiber has many cells, with a common plasma membrane and sarcolemma, or outer sheath with tracheolar invagination for oxygen supply. Contractile myofibrils run the length of the fiber, arranged in sheets or cylinders. When viewed under high magnification, a myofibril comprises a thin actin filament sandwiched between a pair of thicker myosin filaments. The muscles contract

the same way as they do in higher organisms. This includes sliding of actin filaments over myosin. Innervation comes from one to three motor axons per bundle of fibers, each separately tracheated and referred to as one muscle unit, with several units grouped in a functional muscle. There are several different muscle types. The most important division is between those that respond synchronously, with a contraction cycle once per impulse, and fibrillar muscles that contract asynchronously, with multiple contractions per impulse. Examples of the latter include some flight muscles and the tymbal muscle of cicadas. There is no inherent difference in action between muscles of insects and vertebrates, although insects can produce prodigious muscular feats, such as the leap of a flea or the repetitive stridulation of the cicada tympanum. Reduced body size benefits insects because of the relationship between (a) power, which is proportional to muscle cross-section and decreases with reduction in size by the square root, and (b) the body mass, which decreases with reduction in size by the cube root. Thus, the power/mass ratio increases as body size decreases.

### Muscle Attachments

Insects have an external skeleton. Hence, there are stark differences in the attachment of muscles to these skeletons. As musculature is mesodermal and the exoskeleton is of ectodermal origin, fusion must take place. The fusion occurs by the growth of tonofibrillae, fine connecting fibrils that link the epidermal end of the muscle to the epidermal layer. At each molt, the tonofibrillae are discarded along with the cuticle and therefore must be regrown. At the site of tonofibrillar attachment, the inner cuticle often is strengthened through ridges or apodemes, which, when elongated into arms, are termed apophyses. The presence of resilin renders elasticity at the muscle-attachment sites of the cuticle that resembles the vertebrate tendons. Some insects, including soft-bodied larvae, have mainly thin, flexible cuticle without the rigidity to anchor muscles unless given additional strength. The body contents form a hydrostatic skeleton, with turgidity maintained by criss-crossed body wall "turgor" muscles that continuously contract against the

incompressible fluid of the hemocoel, giving a strengthened foundation for other muscles. If the larval body wall is perforated, the fluid leaks, the hemocoel becomes compressible and the turgor muscles cause the larva to become flaccid.

On the basis of location, insect muscles can be classified into intrinsic and extrinsic muscles. Intrinsic muscles can be found completely within the leg, running from one segment to another, whereas extrinsic muscles arise outside the leg. The movement of different parts of the legs is governed by the movements of these muscles. The coxa, for example, is moved by the extrinsic muscles arising in the with promotor and remotor muscles arising on the tergum, abductor and adductor muscles from the pleuron and sternum, and rotator muscles also from the sternum. The intrinsic musculature involves a pair of antagonistic muscles in each segment. In *Periplaneta*, for example, three levator muscles of the trochanter arise in the coxa, whereas there are three depressor muscles, two arising in the coxa and a third arising on the pleural ridge and the tergum. The tibia is moved by the flexor and extensor muscles of the femur and inserted into apodemes from the membrane at the base of the tibia, but the femur itself is immovably attached to the trochanter. Levator and depressor muscles of the tarsus arise in the tibia and are inserted into the proximal end of the basitarsus, but there are no muscles within the tarsus moving the tarsomeres.

The legs of insects are also well equipped with sensory systems. Proprioceptors include hair plates and campaniform sensilla and chordotonal organs. It is well observed in *Periplaneta* and *Carausius*. Exteroreceptors include mechanosensitive trichoid sensilla which is prominently observed in the final larval stages of grasshopper *Schistocerca americana*. Many insects are able climb and hold onto the smooth surfaces due to the presence of adhesive setae. *Rhodnius* and some other Reduviidae have adhesive pads at the distal ends of the tibiae of the front and middle legs. *Epilachna*, there are two pads on the underside of each tarsus. The flexibility of the setae enables them to make contact with irregular surfaces much more efficiently as well as greatly increases the power of adhesion.

Insect legs have been modified for various forms of locomotion. These include jumping,

swimming, digging, grasping, grooming, and stridulation. Digging is best observed in *Gryllotalpa* wherein a very short and broad forelimb is found. The tibia and tarsomeres have stout lobes which are used for excavation. Larval cicadas always have legs for digging or burrowing. They have large, toothed fore femora, the principal digging organs, and strong tibiae which may serve to loosen the soil. Predatory insects have a well-developed leg for grasping. This includes the occurrence of pincers formed by the apposition of tibia on the femur. This feature of grasping is very

prominent in ectoparasites where well-developed claws can be seen. The legs and mandibles are the most widely used for grooming (Fig. 3).

## Locomotion in Insects

The insects move in different modes. The different forms of locomotion are walking, running, jumping, crawling in terrestrial forms, whereas aquatic insects also exhibit unique mechanisms in mechanisms. In order to properly understand

**Insect Locomotion, Fig. 3** Leg muscles. (a) Extrinsic muscles of coxa as seen from the midline of the insect. Muscles arising from the areas marked with diagonal hatching are omitted (from Snodgrass 1935). (b) Intrinsic

muscles. Note that one trochanter depressor muscle is extrinsic (after Snodgrass 1927). (Illustration taken from *Insects: Structure and Function*, R.F. Chapman; 4th edition)

the locomotion mechanisms, it is important to be acquainted with certain terminologies associated with locomotion. They are as follows (Hughes 1952)-

- (A) Protraction: complete movement forwards of the whole limb relative to its articulation with the body.
- (B) Promotion: the movement of the coxa resulting in protraction.
- (C) Retraction: the backward movement of the leg relative to its articulation between the time the foot is placed on the ground and the time it is raised.
- (D) Remotion – the corresponding movement of the coxa.
- (E) Adduction – the movement of the coxa towards the body.
- (F) Abduction – the movement of the coxa away from the body.
- (G) Levation – the raising of the leg or a part of the leg, part of protraction.
- (H) Depression – lowering the leg, or a part of the leg.

- (I) Extension – an increase in the angle between two segments of the leg.
- (J) Flexion – a decrease in the angle between two segments of the leg.

### Walking and Running

A leg can act as a strut, a lever, it can also be used to propel the body forward or backward. When the body needs to stay static, the leg can act as a strut. From the point of attachment of the insect leg to the substratum, an axial thrust is generated. This axial thrust can be resolved into a horizontal and vertical component which provides to forces for the forward motion. But as the insect feet are in contact with the surface of the substratum, it is not allowed to move. But an opposing force at the point of articulation of the leg develops which is equal in magnitude but opposite in direction to the horizontal component of the axial thrust. Since the opposing forces are equal in magnitude, they balance each other out and the insect remains static (Fig. 4).

**Insect Locomotion, Fig. 4** A leg acting as a strut. The axial thrust (a) is exerted down the length of the leg by virtue of the weight of the insect. The size of the axial thrust depends, among other things, on how much of the weight is borne by the other legs. It can be resolved into vertical and horizontal components (b and c), but because the foot is

held by friction with the substratum it does not move. Instead, a horizontal force (d), equal and opposite to force (c) acts on the body and, in this case, tends to push it back unless balanced by other forces. (Illustration taken from *Insects: Structure and Function*, R.F. Chapman; 4th edition)

Insect legs are used as levers to rotate about a fulcrum. Contraction of retractor muscles tends to swing the legs back which generate a force on the ground. This force can be resolved into a vertical and a horizontal component. But due to friction, the feet is held still thus creating a forward force in the body of the insect. The direction of the forward force is such that it pushes the body forwards and upwards (Fig. 5).

**Insect Locomotion, Fig. 5** A leg acting as a lever. Contraction of the retractor muscle tends to swing the leg back so that the foot exerts a thrust (E) on the ground. This can be resolved into vertical and horizontal components (F and G), but since the foot is held still by friction an equal and opposite force (H) acts on the body pushing it forwards and upwards. (Illustration taken from *Insects: Structure and Function*, R.F. Chapman; 4th edition)

**Insect Locomotion, Fig. 6** Extension of the coxotrochanteral and femoro-tibial joints of the hind leg pushes the body forwards. Flexion of the coxotrochanteral and femoro-tibial joints of the foreleg pulls the body forwards. (Illustration taken from *Insects-Structure and Function*, R.F. Chapman; 4th edition)

The forward movement of insects is facilitated by intrinsic muscles which can also exert forces on the body by flexing or extending the legs. If the leg is extended anteriorly, the flexion of the joints will pull the body forwards, whereas if the legs are directed backwards extension of the coxotrochanteral and femoro-tibial joints of the hind leg will push body forwards (Fig. 6).

## Patterns of Leg Movement

The stepping patterns of the insect leg are illustrated by coordinated movement between the left and right forelegs and hind limbs. During slow movements, the legs are protracted singly illustrating the pattern R3 R2 R1 L3 L2 L1 R3, etc. (where R and L indicate right and left, and 1, 2 and 3 the fore, middle, and hind legs, respectively). As the speed of steps increases, a more synchronous pattern wherein three legs, the fore and hind legs of one side and the middle leg of the other, lift together so that the insect can be supported by the other three legs. The three supporting legs form a tripod which allows the insect to maintain balance during the high speed movements (Fig. 7).

Some insects are quadrupedal, which means they can protract the feet of both sides at the same time. At high speed, *Tripidopola* moves by the sequence L1/R1 L2/R2 L1/R1. They maintain stability using their abdomen. Mantids also exhibit this property such that they move in the sequence L3 L2 R3 R2 L3 or L3/R2 L2/R3 L3/R2.

**Insect Locomotion,**

**Fig. 7** Showing the synchrony between the legs on either side of the body forming a tripod. The simultaneous movement implies that protraction and retraction time is same. Thick lines indicate retraction with the foot on the ground, thin lines protraction with the foot in the air. (Illustration taken from *Insects: Structure and Function*, R.F. Chapman; 4th edition)

**Neural Coordination of Leg Movements**

The three neurons (fast, slow, and inhibitory) are active during walking. The example of *Schistocerca* best illustrates this statement. *Schistocerca* lifts its fore foot off the ground at the beginning of protraction, the fast and the slow neurons are activated. This has the effect of extending the tibia as the leg swings forwards. The activity of the slow neuron keeps firing at a moderately high rate through the first half of retraction but the fast neurons are silenced quickly. The activity of the inhibitory neuron peaks during the second half of retraction, when the slow axon is silent (Burns and Usherwood 1979; Wolf 1990).

The alternating movements of protraction and retraction are the result of regular patterns of activity of antagonistic muscles in the different segments of the leg. In *Periplaneta*, for example, the levator muscle of the trochanter is active during protraction, lifting the foot off the ground; the trochanter depressor muscle is inactive but it starts to contract before the foot is placed on the ground while the levator muscle is still active. At the same time, the contralateral depressor muscle is continuously active as this foot is on the ground. Similar patterns of activity have been recorded for other pairs of antagonistic muscles and for other insects (Fig. 8).

**Jumping**

Jumping is observed in the orders Orthoptera, Siphonaptera, Homoptera, and some beetles,

where legs are used for jumping. However, there are orders which do not use legs to jump. These include the orders Collembola, Elateridae, and *Piophil*a (Diptera). The enormous energy required by the legs to jump is generated in the muscles and is stored in the muscle itself as well as the cuticle. Muscular contraction enables the release of the stored energy producing the requisite power.

Jumping in insect is exhibited both in the presence and absence of legs in specific orders. In orders which jump in presence of legs, the example of grasshopper is very prominent. The femoro-tibial joint of the hind leg is adapted in such a way that it allows development of maximum force by the extensor tibiae muscle. The rapid release of energy as a result of this force leads to the sudden extension of the tibia. The extensor tibiae muscle consists of a series of short fibers inserted obliquely into a long, flat apodeme. In *Schistocerca*, many of the fibers of this muscle are innervated only by a fast axon. As a result of their oblique arrangement, a force up to 16 N can be developed as opposed to only 0.7 N by the flexor tibiae muscle. Just above the articulation with the tibia, the cuticle of the femur is heavily sclerotized forming a dark area known as the semilunar process. Beneath the articulation, the cuticle of the femur is thickened internally to form a process, known as Heitler's lump, over which the apodeme of the flexor tibiae slides (Fig. 9).

Insects without the presence of legs are also able to jump. A prominent example is that of

**Insect Locomotion,**

**Fig. 8** Neuromuscular

activity during walking. (a) Activity of the fast, slow, and inhibitory axons to the extensor tibiae muscle of the prothoracic leg of *Schistocerca* (data from Burns and Usherwood 1979). (b) Activity of muscles moving the trochanters of the hind legs of *Periplaneta*.

Antagonistic muscles in L3 are in antiphase, and the depressor of L3 is in antiphase with the depressor of R3. (Data from Delcomyn and Usherwood 1973). (Illustration taken from *Insects: Structure and Function*, R.F. Chapman; 4th edition)

Collembola which can jump using modified abdominal appendages. Arising from the posterior end of the fourth abdominal segment is a structure called the furca, which consists of a basal manubrium bearing a pair of rami, each divided into a proximal dens and a distal mucron. The furca can be turned forwards and held flexed beneath the abdomen by a retinaculum on the posterior border of segment three. The jump is produced by the furca swinging back rapidly to the extended position so that it strikes the substratum and throws the animal into the air. Movement of the furca is produced by powerful longitudinal muscles in the abdomen coupled, in at least some species, with distortion of the cuticle so that it acts like a spring (Christian 1978, 1979) (Fig. 10).

**Crawling**

This form of locomotion exhibits movement by changing the shape of the body rather than movement by legs. It is characterized by the presence of

a soft and flexible cuticle, a hydrostatic exoskeleton, and a turgid body. Most holometabolous insect larvae exhibit such locomotion. Caterpillars provide an excellent example in this regard. Hollow cylindrical outgrowths called prolegs are found in the abdomen of these larvae. The lumen of the proleg is continuous with the hemocoel. An apical area, less rigid than the sides, is known as the planta and it bears one or more rows or circles of outwardly curved hooks, or crochets, with which the proleg obtains a grip. Retractor muscles from the body wall are inserted into the center of the planta so that when they contract it is drawn inwards and the crochets are disengaged. The leg is evaginated by turgor pressure when the muscles relax. On a smooth surface the prolegs can function as suckers. The crochets are turned up and the planta surface is first pressed down on to the substratum and then the center is slightly drawn up so as to create a vacuum (Hinton 1955). Caterpillars move by serial contractions of the

longitudinal muscles which forms a wave from the posterior to the anterior end of the body. Each segment is lifted by contraction of the dorsal longitudinal muscles of the segment in front and its own dorso-ventral muscles, while at the same time the prolegs are retracted (Johnston and Levine 1996a, b; Weevers 1965) (Fig. 11).

## Locomotion in Aquatic Insects

Aquatic insects show a large variety of movement patterns depending upon their structure as well as niche within the aquatic environment. A prominent distinction in locomotion can be observed between insect residing in the

**Insect Locomotion, Fig. 11** Caterpillar crawling. (a) Transverse section through part of an abdominal segment of a caterpillar showing a proleg (Hinton 1955). (b) Longitudinal section through the abdomen of a caterpillar showing a wave of contraction which passes along the

body from behind forwards (left to right) and produces forward movement. Contracted muscles are shown hatched. There are no prolegs on abdominal segment 2 (based on Hughes 1965) (Fig. 12)

substratum compared to insect residing as bottom dwellers and free swimmers. Among the surface dwellers, aquatic Collembolan such as *Podura aquatica* can spring from the water surface using a caudal furca. The Heteropteran *Gerris* can stand over the water surface and row over it using legs which possesses hydrofuge properties (Bowdan 1978). The Coleopteran *Stenus* live in grass stems in mountain streams where it tends to fall frequently. They can walk on the surface of water slowly, however later secretion of five chemicals, most notably “stenusin,” from the pygidial glands, rapid locomotion is also observed. Among the bottom dwellers, larval Anisoptera are quite

prominent. These larvae can walk on the substratum of the water body. These larva however are also capable of escaping through forceful ejection of water by their branchial chambers. The larval case of *Triaenodes* larva (Trichoptera) provides an interesting read. The larval case of the caddis fly, *Triaenodes*, is built of plant material arranged in a spiral, the most anterior whorl of which extends dorsally beyond the rest of the case above the thorax. This dorsal whorl provides a certain amount of lift, helping to carry the case off the bottom. This lift is controlled by the movements of the legs, which tend to produce a downward thrust (Fig. 13).

## Introduction

Morphology is the branch of biology dedicated to the study of form and composition of body parts. It is the foundation of various fields in biology, such as taxonomy and evolutionary studies. There is a deep connection between form and function, considering that the *bauplan* of a species has been shaped for millions of years as a result of physical adaptations to different types of environments and tasks to be executed.

Lineages have a unique history, which is reflected by modifications to existing structures. Terrestrial arthropods, for instance, possess a series of adaptations to live in a dry environment. Total disconnection from the ancestral aquatic environment required a set of evolutionary steps, which include developing stronger and more efficient support and locomotor appendages and physiological and structural adaptations to withstand osmotic stress and allow aerial gas exchange.

The extreme diversity of external form found in insects blatantly portrays a group that has surpassed countless adaptive obstacles. Parallel to this diversity, there is a massive glossary of morphological terms. Knowing all the names for all types of structures and forms can be an arduous task, not only for students but also for experienced entomologists. Hence, a brief description of the most important structures and their variations within Insecta is both necessary and expedient.

## General Body Plan

The insect body is segmented in a series of tandem units, as a result of their metameric teloblastic development. Primitively, these units (metameres) were very similar, each bearing a pair of appendages. However, over the course of evolution, the arthropod *bauplan* underwent significant modifications in which groups of segments clustered and specialized in different functions. Each of these groups of segments is named tagma, and the evolutionary process that originated the tagmata is known as tagmosis. This process likely played a decisive role in the evolution of insects, paving the way for further adaptive radiation.

Metameres in insect bodies are clustered in three tagmata: head, thorax, and abdomen, typically with 5, 3, and 11 segments, respectively. Although segments are usually distinguishable by clear boundaries, traces of their original outlines have largely disappeared in the head. Appendages are present in the head and thorax segments, and in the posterior segments of the abdomen. However, signs of the presence of appendages in an ancestral state can be seen in almost all segments during the embryonic development. Typically, each tagma can be attributed to a specific function: the head receives sensory input, concentrates neural integration, and is

responsible for processing and ingesting food; the thorax is involved in locomotion; and the abdomen is involved in excretion, mating and various sensory functions.

Insect species body sizes range from about 0.25–330 mm in length. However, certain Palaeozoic species grew more than twice that size. Color patterns may vary from drab to vibrant and iridescent. The astonishing diversity of morphological features in Insecta allow different species to run, jump, swim, burrow, and, perhaps most notably, fly—an exclusive feature among all invertebrates.

### Body Wall

An insect's exoskeleton is a hardened case that provides support and protection for soft tissues and organs. Externally, it is composed by a series of plates (sclerites) formed in a process known as sclerotization, jointed by sutures and membranes. Internally, protruding ridges extend from these plates to act as a surface for the attachment of muscles. These heavily sclerotized sclerites work as a protective armor, making it difficult for predators and parasites to pierce through, while also granting protection against adverse environmental conditions.

The body wall, or integument, of an insect is composed of three main layers: basal membrane, epidermis, and cuticle (Fig. 1). The basal membrane is a thin noncellular membrane underlying epidermal cells, which forms the inner lining of the body wall. The epidermis consists of a single layer of ectodermal cells responsible for producing the cuticle. All epidermal cells are glandular and may be involved in a variety of functions,

such as producing silk, defensive and adhesive substances, wax, glandular hairs, milk in viviparous flies and composing various head glands (Chapman 2013).

The cuticle is the outermost layer, made of chitin—a long-chain polymer of N-acetylglucosamine—embedded in a protein matrix. The combination of these molecules is what grants an exoskeleton its rigidity. Variations in the protein matrix composition and molecular architecture explain the diversity of cuticles found between different body parts and across species (Andersen 2010).

Cuticles can have up to three different layers, depending on their position in an insect's body. The sclerotized layer of a cuticle is known as exocuticle, beneath which a non-sclerotized layer called endocuticle is often present. This flexible endocuticle forms the membranes that connect sclerites. External to the exocuticle is the epicuticle: waterproof layers of wax and cuticulin, and a cement layer that protects the wax against abrasion. This cover is essential for terrestrial insects, since it is the primary mechanism that prevents water loss.

Specific parts of the cuticle can be modified to form organs involved in communication. These can produce chemical signals, like the pheromones released in the environment, or visual signals, either composing specialized structures, like the surface of a firefly's lantern, or exhibiting pigmentation and physical colors.

Another important feature of the integument is the externally visible lines that subdivide the sclerites. A sulcus is a groove formed when the cuticle infolds, and an internal ridge (costa)

### Insect Morphology,

**Fig. 1** Schematic drawing of the integument layer of an insect

or rod-like invagination (apodemes) is formed to act as surface for muscle attachment. Carina or crest is a ridge formed by integumental evagination. Whenever two formerly distinct sclerites are fused, the grooves that mark their previous boundaries are called sutures.

## Head

The head of insects is the anterior-most tagma (Fig. 2a). It articulates with the thorax through a flexible membranous neck and bears appendages involved in feeding (i.e., mouthparts) and sensorial (compound eyes, ocelli, and antennae) functions. The ocelli and compound eyes may be secondarily lost in some groups. For many groups, morphology of antennae and mouthparts is an important diagnostic feature.

Historically, the origin of each head segment has been debated among morphologists, though many believe that the current head *bauplan* of insects is the result of the fusion of several segments that were present in an ancestral condition (Headrick and Gordh 2009). Basically, the archetypal segments of an insect's head include seven segments: ocular, antennal, second antennal, mandibular, superlingual, maxillary, and second maxillary (labial). Each is individually innervated by the central nervous system, which is commonly known as the brain. This brain is divided in three main ganglia: the protocerebrum (innervates the eyes), deutocerebrum (innervates the antennae), and the tritocerebrum (innervates the postantennal appendages). Sutures and grooves mark the external surface of the head, and may reflect the original segmental divisions, ecdysial lines or internal inflections. Inflections may extend deep into the head, merging with one another to form an internal skeleton, which strengthens and protects the head, while providing spots for muscle insertion (Chapman 2013). These merged cuticle invaginations are collectively known as tentorium.

## Orientation

Head orientation is determined by the position of mouthparts relative to the rest of the body. Mainly there are three types of orientation: prognathous,

hypognathous, and opisthognathous. The prognathous condition, in which mouthparts are forward-oriented, is commonly found in predatory species (e.g., tiger beetle, Carabidae; antlion larvae, Myrmeleontidae). In the hypognathous condition, mouthparts are perpendicular to the anteroposterior axis, forming a continuous parallel series with the legs (e.g., grasshopper, Orthoptera; praying-mantis, Mantodea), and it is widely considered to be the most likely primitive condition for insects (Chapman 2013). Lastly, in the opisthognathous condition, mouthparts tilt back toward the posterior end, extending between the forelegs (e.g., assassin bugs and cicadas, Hemiptera).

## Compound Eyes, Ocelli, and Stemmata

Typically, insects have ocelli (simple eyes) during larval stages, though they are often present in juveniles and adults. In adults, ocelli usually form a triad or a dyad on the head's anterodorsal surface. Holometabolous insect larvae have stemmata or larval eyes, single-lensed visual organs positioned bilaterally on the larval head. These structures are the precursors of compound eyes during development (Murphy and Moiseff 2019).

Compound eyes are typically present in adult insects. Numerous similar units are called ommatidia, whose number may vary from one to several thousand, aggregate to form these eyes (Chapman 2013). Compound eyes are always paired, though some may be extremely modified and split into two—lower and upper portions—making it seem that there are four eyes (Ephemeroptera, Gyrinidae). They are typically located laterally in the head, with a pair of antennae inserted between them.

Eye size varies greatly between different groups. Occasionally, some species have such large eyes that they even touch each other medially. This condition is called holoptic and generally occurs in Diptera (Acroceridae, Bombyliidae, Pipunculidae, and Tabanidae), but can also occur in males of other orders that swarm and engage in aerial copulation (e.g., some Ephemeroptera). There are cases in which eyes may be completely absent or strongly reduced. Although this is a derived condition, it may occur as an adaptation

to specific environments (e.g., cave-dwelling and subterranean) or lifestyle (e.g., parasitism).

### Antennae

All insects have a pair of antennae, the anterior-most appendages in the head (Fig. 2b). There are many different types of antennae (Fig. 3) and terminology may vary depending on the group. Their function is almost exclusively sensorial, but in some cases, they can bear secondary sexual characters. In soldier beetles, for instance, males possess relatively large antennae, then the larger an individual's antennae are, the higher are the chances of locating suitable females for mating (Mason 1980). The antenna is subdivided into three regions (from base to apex): scape (first antennomere), pedicel (second antennomere), and flagellum. The scape attaches to the head via a membranous socket and articulates via the

antennifer, which is a small sclerotic process. The flagellum is often divided into several flagellomeres interconnected by membranes, and can vary greatly in shape and number depending on the insect group. Using the term segments to refer to flagellomeres is incorrect, since, by definition, the term refers to parts of the body that possess insertion of musculature—such as abdominal and leg parts, except for the tarsomeres (Chapman 2013). In non-insect Hexapoda, intrinsic muscles are present in the scape, pedicel, and flagellum of antennae. These muscles, with the exception of the ones attached to the scape, were lost at the base of the Insecta lineage (Brusca et al. 2016).

### Mouthparts

Insect mouthparts are exposed (ectognathous) (Fig. 2a). The labrum is a movable plate attached to a projected frontal head piece, the clypeous, and

### Insect Morphology,

**Fig. 2** Common structures on the insect head (a) lateral view; (b) detailed morphology of the antenna

**Insect Morphology, Fig. 3** Some types of antenna in insects: (a) setaceous (e.g., bristle-like shape; e.g., dragonflies and damselflies, Odonata); (b) moniliform (e.g., bead shaped; e.g., termites, Blattodea); (c) capitate (flagellum abruptly clubbed at the end, found in butterflies, Lepidoptera); (d) clavate (flagellum is gradually clubbed toward the end; e.g., carrion beetles, Silphidae; pleasing fungus beetles, Erotylidae); (e) filiform (thread-like flagellum; e.g., ground beetles, Coleoptera; grasshoppers, locusts and crickets, Orthoptera); (f) serrate (flagellum saw shaped;

e.g., click beetles, Elateridae); (g) aristate (found in flies, Brachycera); (h) geniculate (antenna is hinged or bent like an elbow; ants and bees, Hymenoptera); (i) lamellate (flagellum ending in nested plates; e.g., scarab beetles, Scarabaeidae); (j) pectinate (flagellum shaped like a comb; e.g., can be unipectinate as some fireflies, Lampyridae; or bipectinate as some moths, Lepidoptera); (k) flabellate (flagellomeres fan-shaped; e.g., some fireflies such as *Amydetes* spp.); (l) plumose (antenna have a feather-like shape; mosquito male *Culex* spp., Diptera)

together they form the clypeolabrum. Mandibles are strongly sclerotized, typically toothed. Maxillae are generally multiarticulate and bear a palp, which may be absent in some species. The labium comprises the fused second maxillae and typically bears two palps. The hypopharynx is a mostly membranous, unpaired lobe. The salivary duct opening is usually located between the hypopharynx and the labium.

The morphology of each mouthpart appendage is related to a species diet, and variation is often used to delimit major insect groups. There are two basic types of mouthparts with several modifications for each appendage: one is adapted for biting and chewing solid food; and the other is adapted for sucking up fluid. In sucking insects, both mandibles and maxillae are transformed into stylets used in perforation of the substrate, or the

mandibles may be entirely lost. In Ephemeroptera and Trichoptera, for instance, adult mouthparts are reduced so these insects do not feed in their adult stage. In Brachyceran flies, the labium is modified into a pair of porous lobes called labellae. Similarly, in Lepidoptera, the maxillae form an elongated suction tube, known as spirignath or spiritrompe.

## Neck and Thorax

The neck or cervix of insects is a membranous region that connects the head to the thorax, providing certain flexibility and freedom of movement to the head. The thorax is divided into three segments (from anterior to posterior): prothorax, mesothorax, and metathorax. Their tergites have the same prefixes: pronotum, mesonotum, and metanotum. When present, the wings originate from the mesothorax and metathorax, articulating with processes on the tergite (notum; dorsal sclerite), and pleura of the somites (body segment). Each of the three thoracic segments bears a pair of legs.

## Thoracic Appendages

### Wings

The wings are specialized organs for flight, found in a variety of shapes, forms, and types. Most winged insect species have two pairs of wings, one on the mesothorax and one on the metathorax. Wings are appendages derived from the insect's integument, and they are most commonly composed of a translucent membrane with veins that contain circulating hemolymph. Some groups may have modifications on either the anterior or posterior wings. Examples of anterior wing modifications include the tegminized wings found in Orthoptera and Dermaptera, which is a sclerotized wing used for purposes other than flight, like defense or stridulation; the elytra in Coleoptera, is a drastic modification in which the anterior wings form a rigid carapace that encases and protects the posterior pair of membranous wings. In Diptera, the second pair of wings is reduced, forming club-like halteres, used as a balance organ during flight. In many lineages, wings

were either shortened, to the point of losing their use for flight (brachypterous), or totally lost (apterous). Furthermore, some lineages may lack the second pair of wings, while the first pair is maintained (e.g., some Ephemeroptera). In Amphiesmenoptera (Trichoptera and Lepidoptera) both pairs of wings are entirely covered in hairs (modified into scales in Lepidoptera).

In fossils, wings are often the only preserved remnants of extinct insects. Wing morphology, especially the study of veins, has been widely used to classify insects. In many groups there were fusions or losses of some veins, with a clear reduction in the ancestral wing venation pattern (Diptera, Thysanoptera). The arrangement of wing veins may be very useful as diagnostic characters, yet the origin and homology of vein distribution is still intensely debated. We can generally recognize six main longitudinal veins: costa (C), subcosta (SC), radius (R), media (M), cubitus (CU), and anal (A); and seven main cross veins: humeral (h), radial (r), sectorial (s), radiomedial (rm), medial (m), mediocubital (m-cu), and cubitoanal (cu-a) (Fig. 4). The areas formed by longitudinal and cross veins are called cells. Some of these cells may have pigmentation and can also receive specific nomenclature depending on the group.

In some insects, both pairs of wings can work together as a single unit. This is possible thanks to hook-like structures between the posterior border of the anterior wings and the anterior border of the posterior wings, such as the hamuli of the Hymenoptera and the frenula of the Lepidoptera, which couples the wings on each side together.

### Legs

All adults of Pterygota have three pairs of thoracic legs, each inserted in a segment: anterior (prothoracic or proleg), medium (mesothoracic or mesoleg), and posterior (metathoracic or metaleg). The legs may be absent in nymphs of Sternorrhyncha (Hemiptera) and in some Holometabola larvae, a condition known as apodous. Insect legs are composed of two parts (Fig. 5): a proximal protopodite (or coxopodite) and a distal telopodite. The protopodite is formed by two elements, a coxa and trochanter, while the

**Insect Morphology, Fig. 4** Hypothetical wing of an insect with the basic vein nomenclature. Longitudinal veins are coded with capital letters, while cross veins are in lowercase letter. See text for abbreviations

**Insect Morphology, Fig. 5** Example of a leg of an insect with the nomenclature of its parts

telopodite consists of four segments, a femur, tibia, tarsus, and pretarsus. The tarsus is commonly subdivided into additional articles known as tarsomeres. There is no intrinsic musculature in the tarsal elements, so they are considered subdivisions of a single original segment. Some adult pterigotes and Holometabola larvae have a single lateral claw on the pretarsi, though the vast majority of hexapods have a pair of lateral claws. Many also have a median arolium, a cushion-like adhesive structure for climbing on smooth surfaces, an unguitrator plate or a medium claw (Brusca et al. 2016).

## Abdomen

The abdomen is the posterior-most tagma in the insect body and, in contrast with the head and

thorax, it is relatively simple in structure and less sclerotized. In many holometabolous larvae, for example, there is no sclerotization and the abdomen is entirely membranous (Diptera, Hymenoptera, Trichoptera, Coleoptera, and Lepidoptera). In the basic *bauplan* of Hexapoda, the abdomen is composed of 11 segments, and can be sorted into three groups: pregenital, genital, and postgenital segments (Gillott 2005) (Fig. 6). The pregenital segments usually lack appendages, and the genital and postgenital segments can be modified for mating and oviposition, with additional sensorial structures.

Each abdominal segment consists of a sclerotized tergum and sternum joined by membranous pleural regions. This membrane increases the flexibility and dilation capacity of the segments, and allows the tergite and sternite to overlap. Tergum, sternum, and pleural elements of some

**Insect Morphology, Fig. 6** Schematic drawing of an abdomen of an insect showing its parts

segments, usually the terminal ones, may fuse to form a complete sclerotized ring (Odonata, Ephemeroptera, Dermaptera, and Machilidae). The sclerotized tergum and sternum may be subdivided, resulting in a series of small sclerites (larvae of *Calosoma* and Trichoptera). An intersegmental membrane connects each segment, allowing longitudinal extension of the abdomen. Segments may also be fused together, wholly or partially (Acrididae and Coleoptera).

Most insects have 10 or 11 abdominal segments; nevertheless, this number is variable among insects with typically reduced postgenital segments. The segment I is also frequently reduced or absent, or even fused with the thorax, as seen in many Hymenoptera. The apical non metameric segment XII, or telson, is found today only in Protura (Chapman 2013).

### Abdominal Appendages

The abdominal appendages are either derived from typical appendages (Lepidoptera and Collembola), or independent secondary structures. In Apterygota and some non-insect hexapods, abdominal appendages are present in all stages of development. Pregenital abdominal appendages are present in Pterygota only in immature stages, and the only appendages seen on adults are those on the genital segments and the cerci (with the exception of male Odonata). Apart from the abdominal appendages related with male and female genitalia, the abdominal appendages in Apterygota and non-insect hexapods may appear as styliform structures, often associated with eversible vesicles.

In addition to water absorption, gas exchange and other functions, abdominal appendages are primarily related with attachment and locomotion, and exhibit a variety of forms and functions, mainly in holometabolous larvae. Prolegs are leg-like outgrowths of the body wall (Symphyta), armed with hook-shaped structures (crochets, Lepidoptera) or digitate in form (Mecoptera). Prolegs count may vary, and when absent, a raised pad armed with spines, called creeping welt, can be found in the same position. In many Diptera larvae, both prolegs and creeping welt are present and are equal in function. The larvae of a number of Diptera families have abdominal suckers, which may be derived from prolegs (Psychodidae, Blepharoceridae). In the larvae of *Maruina* (Psychodidae), these are responsible for anchoring the body in waterfalls. In larval Trichoptera, anal prolegs on segment X are present, and, when fully developed, exhibit two basal segments and a terminal claw; these appendages enable the larva to hold onto its case. Other abdominal structures associated with gas exchange (spiracles), osmoregulation, sensory system, as well as defensive functions, may be present in several groups of insects.

### External Genitalia

The genital segments VIII–XI, together with other terminal structures, are referred to as terminalia. Postgenital segments are typically reduced in insects, and the only indications of an 11th segment are a dorsal lobe, the epiproct, and two latero-ventral lobes, the paraprocts. When the segment XI is present, it forms a conical end piece

that bears the anus at the apex, flanked laterally by articulated cerci (Fig. 6). When the segment is absent, cerci originate in a membranous area between the epiproct and the paraproct.

Cerci are present in Apterygota and hemimetabolous orders, with the exception of hemipteroids. In holometabolous insects, they are found in adults of Mecoptera and some Diptera, but are absent in the larval stage. The shape and size of the cerci may differ between males and females and its morphological variation in male may play an important role in copulation. Contact chemoreceptors and olfactory receptors may be present (Diptera), or even play a role in gas exchange (Zygotera) (Gillott 2005).

The collective of organs specifically related with copulation and egg oviposition is called genitalia. Segments containing the reproductive opening system are usually highly modified. In males, these modifications result in a copulatory apparatus, while in females, they form an ovipositor. The genital opening (gonopore) is located, in the majority of Pterygota, on or behind the sternum VIII or IX in females, and behind the sternum IX in males.

### Male

External elements of male genitalia are very diverse and have considerable taxonomic importance since it is extensively used for distinguishing species. On the other hand, such diversity makes it difficult to understand homologies among some structures and creates a vast variety of names for the many genitalia elements. In general terms, it consists of articulated clasping organs (parameres) arising from a common base (gonobase), and a median intromittent organ (aedeagus), which is often weakly sclerotized. Invaginated within the aedeagus is typically an endophallus, into which the ejaculatory duct enters. During copulation, the endophallus may be everted so that the gonopore is extruded. Phallotreme is the opening of the endophallus through which the semen flows (Fig. 7).

Upon this ground plan morphology, tremendous variation and complexity has evolved in the male genitalia, perhaps driven by sexual selection (Hosken and Stockley 2004). In addition,

**Insect Morphology, Fig. 7** Schematic drawing of a general male genitalia of an insect

modifications such as appendages and spines can operate in coercing unreceptive females to copulate, prolonging copulations, or defending females from takeover attempts by other males (Simmons 2001). Several structures work in protecting the phallus. In many insect groups, for example, the sternum of the last abdominal segment extends to form a subgenital plate. This structure is seen in many groups, but they are not necessarily homologous. In many Plecoptera, there are no claspers, the sexes being held together by the fit of the intromittent organ into the female bursa. Male Archaeognatha, Thysanura, and some non-insect hexapods have no aedeagus, or terminal segments similar to those in females, or exhibit a median phallus, which is bilobed in Thysanura (Chapman 2013).

### Female

As with male external genitalia, there has been considerable variation in the terminology used to describe female external genitalia. When derived from abdominal appendages of segments VIII and IX, it is called appendicular ovipositor and is composed of articulated appendages. These consist of two pairs of gonocoxae (valvifers), each one with a distal

**Insect Morphology,****Fig. 8** Schematic drawing of a general female genitalia of an insect

gonostyli. Where eversible vesicles occur, the genital segments have long, narrow, annulated structures called gonapophyses, or valvulae. The first and the second pair of gonapophyses form the ovipositor axis (Fig. 8). Additional processes may be present in the second gonocoxa; the gonoplace and the gonangulum. In most insects, the gonoplace (or third valvula) has protective and sensory function, but in Orthoptera it is involved in penetrating the substrate in order to oviposit. The gonangulum is a small sclerite that interconnects movements of the first and second gonapophyses, improving mechanical efficiency of the ovipositor (Grimaldi and Engel 2005).

The general condition described above is present in some Archaeognatha, many Odonata and Orthoptera, some Hemiptera (Auchenorrhyncha), and Hymenoptera. However, subsequent modifications also occur in the ovipositor of Pterygota. In Ephemeroptera and Dermaptera, the female has lost the ovipositor and each ovary opens externally via its own oviduct. In some Hymenoptera, the ovipositor can be modified into a poison injector stinger.

In most Holometabola insects, the same elements present in the appendicular ovipositor structure are smaller, and not involved in oviposition. Instead, the terminalia is telescopic in shape, and retraction and extension movements are controlled by muscles of the tergum. It is a substitutive ovipositor called as oviscapit.

## Definition

Insect navigation refers to the ability of many insects to find their way accurately to goals.

## Introduction

Insects, just like many other moving animals, have evolved navigational abilities in order to

accurately move in their environment and exploit the available resources. The spatial abilities of insects have engaged the curiosity of naturalists since at least the nineteenth century. It was found early on that insects could return home from long distances after displacements. Fabre (1882), for instance, marked bees and wasps caught near their nests and displaced them to locations up to several kilometers away. Many of these insects returned home, and they did so even when carried along extensive detours, shaken or rotated in dark containers, or deprived of their antennae. More recently, von Frisch (1965) demonstrated that honey bees that have discovered a rich food source return to the nest and communicate the location of the food source to their nestmates using a waggle dance frequently described as a “symbolic language” (Fig. 1a).

Since then, the development of increasingly sophisticated technologies to track, analyze, and model the spatial movements of insects has provided insights into the mechanisms underpinning these impressive behaviors. A large proportion of behavioral studies has focused on a very few species of social Hymenoptera (ants, bees, and wasps), primarily because of the relative ease of handling, training, and obtaining good quality data sets. These insects show the particularity of rearing young in communal nests from which foragers often take learnt visual routes between productive foraging areas and their nest. The experimental manipulation of foragers at different phases of route formation in the field and in the lab has revealed much of the diversity and complementarity of the guidance systems sustaining insect navigation, also known as the “navigational toolkit” (Wehner 2009). Hence, this entry focuses predominantly on small-scale-foraging navigation by central place foraging Hymenoptera.

## Basic Orientation to Cues

Many if not all mobile organisms have evolved strategies to find favorable environmental conditions within their local environment. Perhaps the first to do so were unicellular organisms climbing gradients of attractants. Similar mechanisms are found in insects in response to olfactory, visual,

**Insect Navigation, Fig. 1** Navigational strategies in insects. **(a)** Path integration information in the waggle dance of the honey bee (*Apis mellifera*) and the homing paths of the Australian desert ant (*Melophorus bagoti*). Both insects use the sun and the polarized light as compass cues. However, honey bees gain distance information through optic flow whereas ants through a step counter.

**(b)** Example of orientation flight around the hive (left) and orientation walk around the nest (right). **(c)** Panoramic images of the habitat of *M. bagoti*. Orientation flights/walks serve to familiarize oneself with the visual surroundings and to learn the corresponding visual cues along a foraging route. (Picture credits: S. Schwarz, honey bee and desert ant, A. Wystrach, panoramic images)

temperature, and humidity stimuli. An insect adopting such a strategy navigates by alternating periods of relatively straight movements with random turns and reorientation. When the insect perceives an increase in the attractant stimulus, the turning rate decreases and vice versa. As a result, periods of straight movements are biased toward the stimulus source. With this strategy, called “kinesis”, the orientation is indirect as the stimulus only yields a change in turning rate or amplitude. Changes can also involve an increase or decrease of speed, which ensures that the insect stays around when conditions are favorable or leaves when they are not.

Also widespread in insects is the production of rhythmic lateral oscillations during locomotion. Interestingly, when coupled with the production of lateral oscillations, kinesis strategies become remarkably efficient at producing a variety of oriented responses (Wystrach et al. 2016). The stimulus perceived still modulates speed or turn amplitude, but the direction of the turn is determined by the state of the oscillator. This simple strategy is enough to climb visual or odor gradients, to track pheromone plumes, and even to follow learnt routes, using visual familiarity to modulate turn amplitude.

Having a bilateral body offers an additional advantage to insects. Signal intensity can be directly compared between the left and the right sensors, and the resulting difference can be used to steer toward or away from the stimulus producing a directly oriented response called “tropotaxis”. Flies, bees, ants, and cockroaches exploit this strategy by turning toward the side where the antenna is exposed to the strongest olfactory intensities, enabling them to climb odor gradients or follow chemical trails. Perhaps surprisingly, cutting an antenna, which in theory should result in constant turns toward one side, has only a moderate effect on trail-following. Single-antenna insects typically manage to maintain a correct overall direction of movement suggesting the existence of other means to maintain a bearing. Indeed, insects can maintain a bearing using global reference cues from the sky. Sky information typically involves multiple cues such as the pattern of light polarization, the gradient of light colors and intensity, the Milky Way, the sun, or the moon itself (Wehner 2009). This ability to maintain an arbitrary orientation relative to a celestial cue is called “menotaxis”.

Whether in humble navigators such as *Drosophila* flies, long-distance migrators such as

locusts and monarch butterflies, or central place foragers such as ants and bees, this ability to maintain a bearing appears to involve a highly conserved brain area called the central complex. The central complex consists of several neuropils forming an elaborate neural network in the middle of the brain. This brain area combines multiple sensory inputs, notably celestial cues, into a unique signal (“bump”) of neural activity. Remarkably, this bump of neural activity tracks the insect orientation by moving along the central complex neuropils as the insect rotates. This bump of activity can be interpreted as a representation of the insect’s current heading. Crucially, the central complex can influence turning behavior by comparing the current heading to a memorized internal directional goal, thus enabling the insect to maintain a straight course relative to external cues. In the absence of celestial cues, the central complex can still track the insect’s current heading using terrestrial cues or even self-motion cues (Seelig and Jayaraman 2015). Other modalities such as wind are also likely to influence the insect’s current heading representation. Such a convergence of multiple directional dictates into one, unique representation of heading direction explains the robustness of insects’ sense of direction.

## Searching Behavior

Sometimes insects may not be able to use any directed navigational routine. This happens when cues are not available, become unreliable, or the animal is inexperienced. It may also happen that the insect fails to find the target or simply gets lost. In these cases, insects can resort to searching behavior.

### Exploratory Search

In their simplest form, searching strategies are based on innate preferences. Mating aggregations of some butterflies, beetles, flies, wasps, bees, and ants occur above prominent objects such as hills or large trees, a behavior known as “hilltopping”. Innate attraction to such prominent locations is sufficient to find them, even in unknown

environments. However, if an unknown area needs to be investigated, insects engage in an exploratory search (Bell 1991). Individuals move along meandering paths which often contain elements of a random walk strategy, such that the choice of step lengths, turning angles or waiting times follows a random process. The path can nonetheless be optimized to whatever resource the insect is looking for. A general characteristic of such searches is that a maximum area is covered with the least effort. This means that the path should cross itself as little as possible and that the unexplored gaps between paths are kept small. The exact spacing and layout of the movement path depends on the sense that is used and how far it reaches, and on the cost/benefit balance of searching an area exhaustively. Even in environments that offer no cues for navigation, the searching insect might know something about the locations it is looking for. For example, it may have learned that some food sources such as flowers occur in patches: if one flower is found by chance, the next flower is likely not far away. One available strategy is to intersperse bursts of short movements to move within a patch, with very long movements to reach the next patch. The movement patterns of some searching insects (honey bees, bumblebees) are now known to have properties of “Lévy walks”, i.e., random walks with a high incidence of long movement steps (Schultheiss et al. 2015). However, it remains unclear whether Lévy walks stem from internal mechanisms or external environmental drivers.

### Systematic Search

An insect that has just navigated to a location but fails to find the target also engages in searching behavior as a kind of backup. In this case, however, the animal has previous knowledge, as it was guided to this location by navigational cues. The point where this guidance ended is therefore the most likely place to find the target or further cues. Bees and ants engage in systematic searching behavior, in which the path is structured in loops around the starting point, to which it repeatedly returns. This looping search expands over time to avoid searching the same area over and again

(Schultheiss et al. 2015). The area covered by this systematic search is also adapted to how precise the insect navigated before getting lost or how “certain” the insect is about its location. The systematic search is restricted to a small area if navigation was precise and covers a larger area if less precise. It thus matches the probability distribution for the target location. The systematic structure of these searches relies on the continued use of navigational routines. To return to the point of origin, the insect needs to track its location in space, e.g., through visual cues or path integration. Some ants and ladybird beetles show indications of a spiral structure in their systematic search paths, which maximizes the area that is covered.

## Path Integration

Bees, wasps, and ants routinely venture out of their nest or hive and search for food and water which they subsequently deliver back to the nest. Those foraging trips are often not straight but winding, and distances can be several 1000 times the insect’s body length (Wehner and Srinivasan 2003). Yet the foragers manage to return to their starting point, i.e., their nest, in a relatively straight line. In other words, they are able to transform information from the meandering outbound trip into a straight inbound trip. This phenomenon is called “path integration”. In order to return in a direct line to a starting point, a continuous update of the direction and distance of the movement trajectory has to be recorded. Insects use a celestial compass system for directional cues and optic flow and stride information as an odometer system. Together, both systems are capable of integrating a homing vector that guides the animal toward the starting point.

Arguably the two most impressive examples of path integration in insects are the waggle dance of honey bees (von Frisch 1965) and the homing behavior of *Cataglyphis* desert ants (Wehner 2009) (Fig. 1a). If a successful foraging bee returns to the hive and wants to promote a worthy food source, it can transfer its path integration information of its last foraging trip to others in the hive. The bee performs a dance consisting of

repeated movements along a shape reminiscent of an eight. The bee follows the shape of the eight and does a waggle run after finishing each loop by rapidly shaking its abdomen from side to side. The angle between the vertical axis of the eight and the waggle run indicates the direction of the food source in accordance to the angle between the sun’s azimuth and the direction the bee should fly once out of the hive. The duration of the waggle run indicates proportionally the distance to the food source from the hive. In terms of ground dwellers, *Cataglyphis* desert ants impressively show that they can efficiently navigate through barren salt-pan habitats with seemingly none or few visual terrestrial cues around them (Wehner and Srinivasan 2003). In both cases path integration helps the insects to either convey navigational information to other foragers or guarantee a “lifeline” for homing in hostile environments. Both behaviors have been exploited by researchers to investigate how insects extract direction and distance information for the path integrator.

## Directional Information: Celestial Compass

For diurnal insects, the obvious celestial cue is the sun and its azimuthal position. Ants, bees, and other insects rely on the sun’s position to determine a heading direction. More than 100 years ago, Santschi (1911) blocked out the real sun and mirrored it to the opposite side of the sky above homing ants, which lead to a 180-degree U-turn in the path of the foragers, showing unambiguously the importance of the sun’s position for navigating ants. Bees are even capable of considering the azimuthal movement of the sun during long and extensive (marathon) waggle dances in which they adjust their directional waggle run axis over time in accordance to the changed position of the sun. For nocturnal insects, the moon, and even the entire Milky Way, can serve as a heading scaffold (Dacke et al. 2003).

The polarized light can also provide insects with directional information. Polarized light creates a distinct pattern that is visible for many insects and can be used for guidance toward a goal location even if the sun is occluded by clouds or the animal is moving through shady areas.

Specific ommatidia (facets) usually located at the dorsal part of the insect compound eye show cellular specializations and sensitivity to polarized light. This “dorsal rim” area helps the insect to decipher the information of the polarized skylight pattern. Ocelli (or simple eyes) between the compound eyes also have polarization processing capabilities in many navigating insects and add to the celestial compass system. Von Frisch (1965) was the first to demonstrate that honey bees are able to use the polarized skylight by showing that after manipulating the visible part of the sky with a polarization foil, bees adjusted their waggle dance direction accordingly.

These celestial compass cues are complemented by a spectral light gradient. The ratio between short and long wavelengths in the sky varies, especially around the sun where the sky shows no polarization but a high amount of long wavelength radiation. While this compass system is less accurate than the sun position or the polarization pattern in the sky, navigating insects can acquire robust directional information for path integration through the combination of several celestial cues.

### Distance Information: Odometer

Directional information from celestial cues is not sufficient for successful homing. Insects also need distance information – an odometer to estimate the correct length of their homing path. Flying insects were first believed to estimate the traveled distance by assessing their energy loss during the outbound trip. Experiments on honey bees loaded with an extra weight of a small ball of steel indicated a greater distance to the food source during their waggle dance than bees without the ball. Later, however, it was found that this response was in fact triggered by the visual input during the foraging flight, as loaded bees probably flew closer to the ground. Bees and other insects rely on optic flow for odometry during path integration. This is well illustrated by experiments testing honey bees in tunnels with either horizontal or vertical stripes on the walls. Individuals trained in tunnels with horizontal stripes on the walls experience less optic flow and indicate shorter distances during their waggle dance than conspecifics trained in tunnels with vertical stripes (Heinze et al. 2018).

Although optic flow is also used for distance estimation by walking insects, it only plays a minor role. Ants primarily rely on a stride counter to measure distances during their foraging trips (Wittlinger et al. 2006). In a series of nifty experiments, foraging *Cataglyphis fortis* ants were shown to overshoot their homing distance when provided with leg extensions, i.e., pig bristles glued to the legs of the foragers serving as stilts. By contrast, ants with truncated legs had a shorter stride length and undershot the distance to the nest in test conditions. Interestingly, walking bumblebees are also able to locate a feeder in total darkness suggesting that they can use nonvisual cues to estimate travel distance.

### Integration of Direction and Distance Information

Neurobiological advances have enabled the characterization of certain areas in the insect brain and their potential functions. The mushroom bodies and the central complex play a pivotal role in path integration in insects. Computational models that incorporate recent new findings of compass and speed neurons are able to explain which brain area may contribute what and when to provide functional path integration in bees (Stone et al. 2017). Compass information and odometric information are integrated in the central complex to gain a heading direction for the foraging insect. After accumulating vector information during the outbound trip, the system can be offloaded to lead the forager back to the starting point or nest, respectively.

### Learning Terrestrial Visual Cues

Many insects learn important locations, such as a profitable food site or their nest, using visual memories of the goal and its surrounding environment, combined with the sensory input or internal state when it is at or near its future goal. The use of visual cues for learning locations was first evidenced by Tinbergen (1932) who showed that the beewolf *Philanthus triangulum* uses objects (e.g., a ring of pinecones) to relocate its nest hole in the sand. If these landmarks are artificially

displaced, the wasp searches at the location of the landmarks.

### Learning Walks and Learning Flights

Besides using single landmarks, insects also perform multiple maneuvers at multiple spatial scales to extract the information from a set of views that allows for visual guidance. Upon leaving its nest for the first few times, a bee, wasp, or ant typically engages in a series of convoluted movements made of arcs or loops covering increasing areas as it moves outward, during which it acquires visual memories of the nest location (Fig. 1b). The insect regularly turns back to face the direction of the nest or prominent nearby landmarks. During these turns, an individual could potentially be acquiring panoramic snapshot views of the goal location (Zeil and Fleischmann 2019). At the end of these maneuvers, bees change their flight altitude by gradually gaining height until they fly above surrounding objects, possibly increasing the reach of their visual memories to include the more distant panorama. Once the insect has learnt views of the nest surroundings, it can later engage in successful homing. These panoramic views are used for long-distance navigation toward the location of the hive (Fig. 1c). Bumblebees often approach the goal in a type of zigzag flight so that the visual patterns during the turns match those of the turns in the learning flight. This putative “parallax-matching” means that the insect searches for the nest (or goal) at the correct metric distance from the surrounding visual cues.

### Route Following

To get from one particular place to another, insects often develop routes. The majority of ants are simply able to follow a pheromone trail deposited on the surface by a conspecific. Such behavior is entirely based on tropotaxis and requires no previous experience. However, thermophilic desert ants do not lay pheromones and develop visually guided routes that allow fast, reliable, and safe passage to and from profitable feeding sites. Essentially, such a route is a series of navigational instructions. With experience visual cues can override the home vector

information established by path integration, as seen in the desert ant *Melophorus bagoti* (Kohler and Wehner 2005). Individual foragers learn and maintain idiosyncratic routes leading them from the nest to a feeder and back again. The outward route of an ant can be distinct from the returning inbound route back to the nest. Ants displaced along their route or encountering their route during search behavior seem to be able to follow it starting from any point along it. In the European desert ant *C. velox*, individual foragers learn multiple inward and outward routes through their habitat (Mangan and Webb 2012). These routes are learned rapidly, stored in long-term memory, and recalled for guidance as appropriate given the correct visual cues are presented to the ant. Learning multiple paths through the habitat over successive journeys provides a mechanism by which ants memorize a series of interlaced courses and thus perform complex navigation.

During the process of route formation, insects tend to gradually adjust their path in order to reduce travel distances. This optimization is evident in bees that exploit multiple small but regularly replenishing patches of flowers over large territories. Orchid bees, bumblebees, and honey bees were all found to develop multi-destination routes linking multiple feeding locations using a stable visitation sequence called “traplines”. When allowed to forage on a stable array of ever replenishing feeders for several consecutive hours, individual bees attempt to take the shortest possible route to visit all locations once, a spatial optimization task akin to the traveling salesman problem (Lihoreau et al. 2012). Unlike mathematicians, bees cannot compute and compare the absolute distances of all the possible routes to solve this task (there are over three million possible routes for visiting ten feeders). Rather, it has been proposed that insects assess overall travel distances between all flight legs between feeding sites, using path integration and visual memories, and refine their routes through trial and error. This iterative improvement approach replicates the behavior of naïve bees displaying many revisits to feeders and that of more experienced bees following near-optimal routes.

## Integration of Multiple Navigational Cues

Information can be transferred between different navigational strategies. This is the case when insects are following patchily distributed orienting cues and need to decouple their body orientation from their travel direction. Wasps and hoverflies fly forward toward a goal by matching their currently perceived view with their memorized views. To pinpoint the exact location of the goal, insects intersperse transverse sweeps to search for further cues. Another example is backward-walking ants that are pulling large prey items to the nest. Ants regularly drop the prey briefly and turn around to get a nestward view. In both cases (flying wasps/flies and walking ants), the insects orient themselves by aligning views and then transferring the derived travel direction to a compass system that works independently of body orientation (Schwarz et al. 2017).

Depending on context, navigating insects can also switch flexibly between different guidance strategies. Path integration, for instance, is prone to accumulating errors, especially with increasing travel distances. For many insects, this strategy may provide a sound scaffold for long-distance travel and direction, complemented by systematic searches and panoramic landmark guidance to pinpoint a location such as a small nest entrance or a blossoming flower at finer scales. However, in the real world, different navigational tools rarely operate in isolation. Multiple cues are often available at the same time, or currently perceived cues need to be reconciled with previously stored memories. Many insects are therefore able to integrate different navigational dictates, which is especially evident when they are set into conflict experimentally. This is, for example, easily achieved in navigating ants by displacing terrestrial visual cues or displacing the ants, as this puts the visual route guidance strategy in conflict with the ants' path integrator. Integration of navigational dictates usually leads to intermediate directions, with separate cues being weighted optimally according to their salience or reliability. One prominent strategy may therefore dominate the integrated output, as was the case in Tinbergen's experiments with

beewolves (Tinbergen 1932). Based on our current understanding of how navigational strategies operate and interact, recent models suggest that such an integrating navigational toolbox has a decentralized architecture (Hoinville and Wehner 2018).

## Conclusions

The majority of experiments on insect navigation have been performed on a very few species of social Hymenoptera, chosen because of the relative ease of handling, training, and obtaining good quality data sets. These experiments suggest that impressive navigational behavior can be explained by a relatively simple navigation toolkit comprising a series of interconnected navigational units in a modular architecture (Wehner 2009). Future investigations of the neural mechanisms underpinning navigation, using modern techniques for genetic engineering, brain recording, and controlled behavioral experiments in virtual reality setups, should help identify this modular organization and how it controls behavior. These approaches, available in model organisms (e.g., *Drosophila*), will indicate to what extent principles of navigation identified in Hymenoptera are common across insects.

## Introduction

Insects are the richest organisms on earth in terms of species, biomass, and distribution (Goulson 2019). Such richness is highly associated with morphological, ecological, and behavioral diversity, along with lineages diversifications that have been driven by coevolution with angiosperms (Hunt et al. 2007), which make insects the main pollinators and great dispersers. To play that role, along with many others, insects evolved simple, connected sensory organs, which receive and filter

the information around and process it differently according to the context. These organs are involved in the insects' evolutionary success and promote a perception of the environment through their stiff exoskeleton. As such, and due to their thick physical barrier, insects rely upon a range of mechano- and chemosensory structures, both spread throughout the major axis of their body.

The insect's sensory systems have been extensively investigated, mainly from model organisms, such as *Drosophila melanogaster* Meigen, 1830. Research has uncovered several structures and genes, leading to characterization of several sensory-motor pathways, as well as a better understanding of their roles (Schnaitmann et al. 2020; Mohapatra & Menz 2019). Noteworthy, these canonical studies paved the way for recent surveys on sensory systems in a variety of extant taxa, a soaring effort that has been shedding light on the role of evolution in different systems (e.g., visual) and typical genes involved (e.g., *Opsin*). Likewise, other model organisms also fill important gaps (e.g., *Tribolium castaneum* [Herbst, 1797], *Cloeon dipterum* [Linnaeus, 1761]) on how multiplexity in sensory systems and structures, and also evolutionary novelties, arise in insects as a whole (Altincicek et al. 2008; Almudi et al. 2019). These kinds of studies were, and still are, mostly focused on insects, especially because they dwell in a diversity of environments and habitats, and most of them undergo metamorphosis in different environments from which they emerge. For example, larvae usually are physiologically, morphologically, and ecologically unique from adults, especially in cases when each larval stage develops in different environments, requiring other resources for that. Therefore, a variety of mechanisms, structures, and consequently mechano- and chemoreceptors are required for sensing environments.

Insects display a range of organs and structures known to play a role in perception, from the external surface of their body to internal organs, which can fall into two major sets of receptors: mechano- and chemoreceptors. Mechanoreceptors usually are hair-like projections from the cuticle which arise from a socket that permits

movement. In this regard, movement triggers neural stimulation resulting in perception. Chemoreceptors deal with the environment from olfaction and contact chemoreception (gustation or taste). An array of chemoreceptors is spread over the cuticle and is sensitive to different scents and chemicals. These receptors are usually used in contexts other than feeding, being able to detect chemicals in solutions and dry surfaces, important to gathering information from the surroundings. However, processing this information is rather different within the central nervous system. Differently, visual systems, communication, and temperature perception rely on other structures, such as visual organs, antennae, and legs.

Visual or chemical communication can be driven by the context, warning predators or attracting partners. Therefore, itemizing which components play a role in sensory organs, and how it occurs can be a challenging task even for experts. The extreme diversity of forms and functions in insects portrays the countless, and extremely complex, structures involved in the sensory system. Therefore, the main goal of this chapter is to characterize the principal components involved in the insect's sensory system, how each element is triggered according to the context, and their respective role in a variety of taxa.

## Nervous System

### Basic Elements

A complex nervous system, such as those of the insects, are characterized by a variety of specialized cells responsible for processing information, driving impulses, promoting the functional integration of organs and systems, and generating specific behavior in appropriate response to the environment (Oland & Tolbert, 2003). The insect's nervous system consists of a brain located in the head, and a nerve cord located ventrally, with ganglia in each segment (Fig. 1). Nerve cells communicate through synapses with the action of neurotransmitters, such as acetylcholine.

The first basic element is the nerve cell, or **neuron**. The neuron consists of a cell body called

**Insect Sensory System, Fig. 1** Central nervous system of a hypothetical insect. (Adapted from Brusca et al. (2016))

**soma** or **perikaryon** containing mitochondria, a rough endoplasmic reticulum, and Golgi complexes. From the soma one or more cytoplasmic projections extend to make contact with other neurons or with effector organs, mainly muscles. These projections can be **dendrites**, responsible for the reception of incoming signals, or a long process called an **axon**, which conducts signals over long distances and is responsible for passing on signals to other neurons or effector organs. Neurons can be monopolar, bipolar, or multipolar and the type of neuron varies according to the region and its function. For example, most neurons from the central nervous system are monopolar, the peripheral sense cells are bipolar, and multipolar neurons occur in the ganglia of the nervous system (Chapman et al. 2013).

In addition to neurons, the nervous system also includes a variety of **glial cells**. Glial cells surround neurons with one or more folds, sometimes as several cells folded over themselves. Some neurons do not have glial cells surrounding them. As in vertebrates, the insect glial cells are normally outnumbering neurons in the central nervous system (Saint Marie et al. 1984). However, when compared to mammals, for example, the nervous system of insects has far fewer glial cells, about 10% of the cells of the central nervous system in an adult fruit fly (*Drosophila melanogaster* Meigen, 1830) (Edwards & Meinertzhagen, 2010) and 90% of brain cells in mammals (Blinkov & Glezer, 1968). In addition to the nursemaid role long been assumed (Hoyle, 1986), the functions of glial cells go beyond the protective role for neurons, such as: (i) assisting

neuronal development by providing trophic support; (ii) reference points for axonal location; (iii) maintenance of cells; (iv) neuronal isolation; and (v) regulation of extracellular space around mature neurons by acting in neurotransmitter clearance and recycling as well as in ionic regulation (Edwards & Meinertzhagen, 2010). In this context, changes in glial function can affect different behaviors in relation to locomotion, sleep cycles, and mate choice, for example.

### Brain

The insect brain is characterized by an anterior area with ganglion fusion. Like the general plan for arthropods, the insect nervous system is divided into three regions, each of which originates from a pair of coalesced ganglia: the **protocerebrum**, the **deutocerebrum**, and the **tritocerebrum** (Fig. 2). Each of these regions is responsible for innervating certain head appendages. The protocerebrum is the most anterior region, comprising most of the brain mass and innervates the eyes. It is bilobed and extends laterally to the **optic lobes**, which in turn extend to compound eyes. The deutocerebrum contains the antennal lobes – which receive olfactory stimuli, the antennal mechanosensory, and motor center. The tritocerebrum is the smallest part of the brain, consisting of two lobes located beneath the deutocerebrum. From it, the periesophageal connectors bypass the esophagus and connect to the lateral regions of the subesophageal ganglion.

In addition, insects have a hypocerebral ganglion between the cerebral ganglion and the foregut, which is associated with two pairs of

**Insect Sensory System, Fig. 2** Frontolateral view of the brain of a locust (Orthoptera), showing the three regions of the brain (protocerebrum, deutocerebrum, and

tritocerebrum) and the most important connectors, ganglia and nerves. (Adapted from Brusca et al. (2016))

glandular bodies of important endocrine function: **corpora cardiaca** and **corpora allata**. Together with the prothoracic glands and neurosecretory cells of the protocerebrum, they form an important endocrine center that regulates growth, metamorphosis, and other functions (Brusca et al. 2016). The corpora cardiaca stores and releases neurohormones, such as prothoracicotropic hormone, which stimulates the secretory activity of the prothoracic glands. Corpora allata, on the other hand, is responsible for the secretion of “**juvenile hormone**,” the main hormone involved in the insects’ moulting and metamorphosis, which opposes or prevents the metamorphosis of immature insects (Williams, 1956). However, the biological action of the juvenile hormone is observed only in the presence of active prothoracic glands or its secretory product, ecdysone (hormone responsible for inducing moulting in insects) (Williams, 1959).

### Peripheral Nervous System

The peripheral nervous system is formed by nerves that leave or reach the central nervous system to innervate muscles or sense organs. That is, it is responsible for receiving all external stimuli and sensations and establishing an

immediate communication with the brain. The nerves can be of two types according to their function: (i) **afferent**, or sensory, when they arrive at the central nervous system, bringing information about the stimulus received by the sense organs, and (ii) **efferent**, when they leave the central nervous system and give instructions to muscles and appendages.

### Stomodaeal Nervous System

The stomodaeal (or stomatogastric) nervous system (SNS) is the anterior portion of the insect nervous system, characterized by innervating the visceral organs through a peripheral complex of ganglia and nerve fibers, being closely linked to the brain and the endocrine system (Ayali, 2009). In general, the SNS innervates the muscles of the mouth cavity, foregut, and midgut, and regulates food uptake and food transport (Hartenstein, 1997). Within this context, the behavior related to food, that is, the different variations of the motor pattern appropriate to the various types of food and food particle consistencies, is the primary physiological role of the SNS. Because it is considered a plesiomorphic character, being present in all higher invertebrates (starting with

Annelida), the SNS is of interest from an evolutionary perspective for comparative studies on the nervous system (Ayali, 2009).

The main ganglion of this system is the **frontal ganglion**, located in front of the brain (Fig. 2), playing a key role in the control of foregut movements (Ayali, 2004). Studies examining the effect of frontal ganglion ablation on the behavior and development of the insect have shown its fundamental function in the passage of food through the anterior intestine and in crop (i.e., area of the foregut where food is temporarily stored for enzymatic digestion) emptying (Ayali, 2004). However, in addition to its function in feeding, the frontal ganglion is fundamental in another important behavior of insects, namely moulting and ecdysis. In this regard, the SNS has also a role in moulting, by increasing the internal air pressure in the digestive tract, acquired by swallowing air during ecdysis in aerial arthropods (e.g., allows the external cuticle to detach from the new). Likewise, aquatic arthropods swallow water for subsequent cuticle division (Ayali, 2009).

Interestingly, the formation of the SNS has many parallels with the development of the vertebrate peripheral nervous system. In addition to having functions comparable to the vertebrate autonomic nervous system, the development of SNS in insects has similarities with the neural development in vertebrates, in particular the neural crest and sensory placodes (for more detailed information, see Hartenstein, 1997).

## Perception and Sense Organs

Insect perception is mainly driven by neural and glandular reactions in response to stimuli from the environment. All insects have sense organs that make it possible to detect scents, sounds, produce images, etc. The signals generated by the receptors of the sensory system travel to the brain where an appropriate behavioral response is generated according to the necessity, such as avoiding danger, foraging (i.e., search for prey/food), finding a mate, and reacting to environmental changes, among many others.

Receptors of the sensory system can be divided into two categories: (i) **exteroceptors**, which detect external stimuli, and (ii) **interoceptors**, which detect signals from the body itself. Proprioceptors, which detect changes in the position of the body or body parts, are a type of interoceptor. Receptors are also classified in terms of functionality and direction of impulse (**mechanoreceptors**, **chemoreceptors**, and **photoreceptors**).

### Mechanoreception

Mechanical stimulation is caused mainly by pressure and air displacement to detect sound, deformations of body regions, movements, vibrations, or other mechanical disturbances, which can either be caused by external forces or by self-produced movements (Keil, 1997). In arthropods in general, stimuli are processed by the distortion or flexion of bristles and membranes arranged along the body. Mechanical stimuli serve several different purposes, such as: (i) sound receptors can be involved both in intraspecific communication (for example, the song crickets and cicadas), as well as in the avoidance of predators (e.g., moths avoiding bats) or certain parasitoids (e.g., caterpillars avoiding wasps); (ii) air current receptors may be involved in alarm behavior (e.g., by filiform hair on the cerci of crickets and cockroaches) as well as prey detection (e.g., trichobothria of spiders); and (iii) touch receptors (bristles) report direct mechanical contact, but are also involved in regulating body position (e.g., hair plates around the neck of bees and flies) (Keil, 1997).

### Sensors

Sensors are basic functional units composed of receptors. They usually have a cuticular portion, with one or several neurons, and peripheral cells. The most common types of mechanoreceptors according to cellular, subcellular, and cuticular organization are: (i) **tactile hair** or **bristle**; (ii) **hair plate**; (iii) **campaniform sensillum**; and (iv) **chordotonal organ** (for reviews and pictures see Keil, 1997 and Tuthill & Wilson, 2016).

Trichoid sensors, usually referred to as bristles or tactile hairs, are the most common

exteroceptive organs on the body surface. These are elongated structures, with the base wider than the tip. They have two pores, a terminal and a basal one, in which the latter is in direct contact with the nerve cell. Just below the bristle, there is a cavity filled with lymph, which reinforces the signal captured by the cuticular structure from the movement of the bristle (Chapman et al. 2013). As the most common and abundant mechanoreceptor in the body of insects, the bristles are associated with a wide range of behaviors in insects. The movement of tactile hair can serve as an alert to the presence of foreign objects, such as dirt and parasites, on the body surface (Tuthill & Wilson, 2016). The stimulation of the bristles can be involved in detection of strong air currents in locusts (Camhi, 1969a, 1969b) and can detect wind, courtship song, and the wingbeats of a predator in crickets and cockroaches (Tuthill & Wilson, 2016). The bristles modified on the cerci of crickets and cockroaches are also called **trichobothria**. They are long relative to the diameter and, unlike the usual trichoid sensors, do not taper (Chapman et al. 2013).

In addition to individualized bristles, they can occur in small groups of short, stiff, and parallel hairs, each of which is innervated by a single sensory neuron, in which they are called hair plates. They are often positioned at folds in the cuticle, being deflected during joint movement (Tuthill & Wilson, 2016). In *Drosophila* it functions as a proprioceptor found in the joints of the legs (Pringle, 1838), while in cockroaches it can function as an exteroceptor at the base of the antennae (Okada & Toh, 2000).

Campaniform sensillum do not have elongated cuticular structures like the bristles. Instead, they have a malleable cuticle, called **dome**, which is composed of three layers: a thin outer layer, a porous middle layer, and a more fibrous internal layer. An articular membrane surrounds the dome. These small domes detect tension and compression in the surrounding cuticle and they are often found grouped in areas where disturbances in the cuticle are likely to be high, such as in the proximal regions of the leg and antennae, which are regions subject to torsion (Tuthill & Wilson, 2016). The nerve cell binds to the three cuticular

layers through the dendrite, which is responsible for transmitting the signals received (Chapman et al. 2013). Studies have shown that campaniform sensilla plays an important role in coordinating joint movement both within a leg and across legs, and that natural tripod gaits are shaped mainly by sensory feedback to motor circuits (Tuthill & Wilson, 2016), and not by sensory neurons present in the legs (e.g., *Drosophila melanogaster* is not affected in tripod gait and left-right coordination when its neurons are deprived in the legs [Mendes et al. 2013]).

Chordotonal, or scolopophorous, organs are structurally complex mechanoreceptors distributed throughout the insect's body, working to detect a wide range of mechanical stimuli, from gross motor movements to airborne sounds (Yack, 2004). Chordotonal organs include several types of mechanoreceptors in which one or more bipolar neurons establish a connection between two internal surfaces of the exoskeleton. Along with each bipolar neuron there are two other cells forming a sheath (the **escolopale** cell) and an attachment point (the **cap cell**). Together, these three cells create a unit called **scolopidia**, which can occur individually or, most commonly, in groups of similar units. The scolopale cell contains the scolopale, a ring or a series of rods made of fibrous material. The neuron is triggered by the movements of the scolopidium's apex. Common types of these organs are: Johnston's organ, tympanal organ, and subgenual organ.

The **Johnston's organ** is the largest chordotonal organ found in insects and is located at the base of the antenna, between the pedicel and the first flagellum of most species, although they are particularly prominent in individuals of the order Diptera – flies and mosquitoes. The structure is formed by one or several masses of scolopidia, which respond to movements of the flagellum relative to the pedicel and the number of scolopidia in one Johnston's organ in different insects' groups can vary from 30 to 5000 (Schmidt, 1972 *apud*. Jeram & Pabst, 1996b). In many insects, Johnston's organ functions as a proprioceptor, monitoring the position and movements of the flagellum according to the active or passive movements of the antennae and body (Jeram & Cokl, 1996a) and to detect air particle

vibrations from near-field sound sources (Sane & McHenry 2009). In male mosquitoes (order Diptera, family Culicidae) and chironomid midges (order Diptera, family Chironomidae) it functions as auditory organ to detect flight sounds of conspecific females in mating behavior (Burkhardt & Gewecke, 1965; Yack, 2004). In flies (order Diptera, family Calliphoridae) and locusts (order Orthoptera), the Johnston's organ is involved in controlling the speed and direction of flight. Interestingly enough, in dancing honeybees (*Apis mellifera* Linnaeus, 1758) Johnston's organs are responsible for detecting the airborne sound close to the field generated by the wings during the waggle dance and used to transmit information to other bees about the sources of nectar in the environment (Dreller & Kirchner, 1993). Finally, it can act as a gravity receptor, controlling the position of the body in water, in water bugs (order Hemiptera, family Belostomatidae), and as a detector of water currents in other aquatic insects (Jeram & Pabst, 1996a).

Groups of insects such as crickets, bees, grasshoppers, and some flies have independently evolved auditory **tympanal organs**. The tympanic organs are chordotonal organs specialized in detecting pressure waves from distant sources of sound (Sane & McHenry, 2009). They consist of a thin cuticular membrane stretched through a sac filled with air. Chordotonal organs attached to the tympanic membrane detect high-frequency mechanical vibrations (2–100 kHz), acting in a similar manner to a vertebrate's eardrum. Insects that do not have tympanic organs depend on Johnston's organ for detecting sound, limiting their hearing to lower frequencies (<1 kHz) (Tuthill & Wilson, 2016).

The number of scolopidia present in tympanic organs varies widely within insects, from a single scolopidium found in *Plea* Leach (order Hemiptera, suborder Heteroptera) to more than a thousand in some cicadas (order Hemiptera, suborder Homoptera) (Marques, 2012). In addition, tympanic membrane can be found in different parts of the body, as in the legs of crickets and bush-crickets, in the abdomen of grasshoppers and cicadas, and in the thorax of moths (Snodgrass, 1926; Sane & McHenry, 2009).

Finally, another specialized chordotonal organ found in most insects is the **subgenual organ**, which is a fan-shaped array of scolopidia located in the proximal part of the tibia (Tuthill & Wilson, 2016). This organ is sensitive to vibrations of the substrate upon the animal stands. In cockroaches and ants, the subgenual organ is extremely sensitive, playing an important role in perceiving vibrations emitted by possible predators, and in some cases, intraspecific substrate-borne sound communication, as in the green lacewing, *Chrysoperla carnea* (Stephens, 1836) (order Neuroptera, family Chrysopidae), (Devetak & Pabst, 1994) and in stink bugs (order Hemiptera, family Pentatomidae) (Čokl, 1983).

### Chemoreception

It is the detection of chemical stimuli, either through **olfaction** (chemical compounds commonly carried by air) or **contact chemoreception** (gustation or taste) which is transmitted by solutions or dry surfaces. The functional distinction between olfaction and contact chemoreception is usually clear, based on the characteristics of the stimuli (volatility), the means of transport (water versus air), and the morphology of the sensillum (Stadler, 1984). In addition, processing within the central nervous system is quite different for olfaction and contact chemoreception. However, olfactory receptors can respond to substances in solution and contact chemoreceptors can respond to high concentrations of some odors (Chapman et al. 2013).

### Olfaction

Olfaction is the ability to detect compounds in the gaseous state, and insects have a wide range of receptors sensitive to odors. Insects can detect odor through the antennae and the maxillary and/or labial palp. The importance of olfaction for insects is very evident mainly through the existence of different forms of antennae. Basically, the distal segment of the antennae and the palpi is covered with olfactory sensilla of different shapes and structures. Insect antennae probably evolved from structures that were predominantly mechanosensory. While the antennae of primitive terrestrial arthropods have intrinsic musculature,

responsible for the great flexibility of movement, they have a low number of sensilla, presenting a very ineffective chemoreception capacity. On the other hand, the insect's antennae are rich in sensillum, but lack intrinsic musculature, being in most lineages specialized structures for the detection of odor molecules (Schneider, 1964; Hansson & Stensmyr, 2011). However, there are exceptions such as the water scavenger beetles (family Hydrophilidae, order Coleoptera), whose antennae do not actually have an olfactory function but functions as an auxiliary breathing apparatus, which are used as oxygen replenishment reservoir located in a cavity between the elytra and the abdomen, where the respiratory spiracles are located (Hrbáček, 1949). In some groups, the sound detection function by the antennae is evident, along with the olfactory function. Mosquitoes are a good example in which the evolution of antennal morphology was most likely driven by an olfactory and hearing demands (Wheelwright et al. 2021).

There are several types of olfactory sensillum, the most common of which are the **trichoids**: long, thin-walled (0.5 micrometers or more) hair-like structures without a socket at base. Other shapes have also been described as follows: **basiconic**, which are shorter projections than the trichoids, digitiform, and with thinner wall (0.3 micrometers or less); **placoid**, continuous plates arranged in the internal integument; and **celloconic**, which are projections arranged within small cuticle invaginations (Chapman et al. 2013).

Cuticles are multiporous. These pores allow the detection of odorous substances. The main difference between mechanoreceptors and chemoreceptors is the number of pores, which help in the capture of olfactory substances, along with the dendrites inside the sensor, reaching the pores.

#### Contact Chemoreception

A strong feature of contact chemoreceptors is that they are internally hollow and, unlike the olfactory sensilla, they have only one pore at the tip. It is through this large apical pore that stimulating chemicals reach dendrites of the gustatory receptor neuron. A clear example is during feeding. The

sensilla of the insect's mouthparts is usually bathed in the fluid released by the food during feeding, which generates a response by neurons to chemical substances in solution, being comparable to the taste receptors in the mouth of vertebrates (Chapman et al. 2013).

Although they may have very different external shapes, the most common contact chemoreceptor is a trichoid bristle. Normally, bristle sensilla have sockets similar to those of mechanoreceptor hairs that provide some motility. More rarely, contact chemoreceptors can also be basiconic, in this case not having a socket and being continuously surrounded by the insect's cuticle.

Chemoreceptive contact sensilla are found in the main parts of the body, but most are located in the mouthparts and tarsi (more distal segments of the legs, anterior to the claw when present). However, chemoreceptive contact sensilla have already been identified in the wings, ovipositor, and antennae (see Stadler, 1984). Basiconic sensilla are most commonly found in the feeding channel, that is, inside the mouthparts (Chapman et al. 2013).

The gustatory organs of blood-feeding mosquitoes, for example, include the tarsal segments of the legs, the labellum and labrum of mouth parts, and the cibarium, an internal organ of the head responsible for sucking. The sensilla found in the tarsi of the legs are responsible for the first detection with a potential source of blood or oviposition site. Once the food source has been found, the needle-shaped labrum pierces the prey and then the contact of blood chemicals will be made through the sensilla of the labellum and the cibarium (Baik & Carlson, 2020).

#### Photoreception

Insects can perceive light from different optical and dermal structures. The most common structure is the **compound eye** (Fig. 3a, b). However, other structures, such as the **ocelli** (Fig. 3a, b) and **stemmata** (Fig. 3c, d) are also found in insects. Stemmata are found only in the larval phase of holometabolous insects (i.e., type of development where larval morphology is completely dissimilar from that of the adult, having a pupal stage between the larval and the adult phases).

**Insect Sensory System, Fig. 3** Photoreceptive organs in insects: compound eye (black arrow), ocelli (red dashed line), and stemmata (blue arrow). (a) male subimago of mayfly of the genus *Thraulodes* showing its surprising compound eyes divided into two portions (an upper portion and a lower portion) and triad ocelli. (b) adult female

of dobsonfly of the genus *Corydalus* with emphasis on compound eyes and ocelli in triad. (c) aquatic dobsonfly larvae of the genus *Corydalus* showing the stemmata. (d) saturniid caterpillar showing the stemmata (Family Saturniidae). (Pictures were kindly provided by Frederico F. Salles (Universidade Federal de Viçosa, Brazil))

All eyes originate from embryonic ectoderm and they have similar basic structures. Eyes are composed of an optical portion and a nervous portion. The optical portion specializes in capturing light and the nervous portion specializes in transducing and translating the light signal.

#### Compound Eye

The compound eye is the main and most developed photosensitive structure in insects. Most adult insects have a pair of compound eyes, which can be greatly reduced or absent in parasitic groups and in many cavedwelling forms (Brusca et al. 2016). Compound eyes are composed of smaller units, called **ommatidium** (Fig. 4a). The number of ommatidia per eye can vary from 800 in drosophilids to 20 thousand in some dragonflies, and the number of ommatidia determines

the visual acuity of the compound eyes (Marques, 2012). A single ommatidium consists of two elements: an external optical part composed of a **lens** and a **crystalline cone**, and an internal sensory part composed of a **rhabdom** and **sensory cells** (Brusca et al. 2016; Chapman et al. 2013).

Below the lens is the crystalline cone, formed by four **Semper cells** and surrounded by two **pigmented corneagenous cells** (Triplehorn & Johnson, 2005). The retina is the eye's innermost part, and it is a junction of seven to nine elongated neurons called **retinular cells** (or **sensory nerve cells**), the photoreceptors cells. The peripheral part of each retinular cell is a set of tightly packed microvilli called **rhabdom**, a light collection area that converts light energy into nerve impulses. The retinular cells are surrounded by several (12–18) secondary pigment cells, which isolate

each ommatidium from its neighbors (Brusca et al. 2016).

Insects have two types of eyes: **apposition eyes** or **superposition eyes**. These differ in relation to the distance between the sensory cells and the lens, which vary according to the insect's habitat. Most diurnal insects have the sensory receptor cells ending close to the lens (Fig. 4b). In this case, the pigment surrounding one ommatidium extends along its entire length, then the light reaching a rhabdom comes through only this one ommatidium. As a consequence, the image formed is in mosaic, in which each ommatidium forms an equal image. In contrast, most nocturnal insects have eyes with a clear zone between the lenses and the sensory receptor cells (Fig. 4c), forming a much brighter image than the apposition eye (Chapman et al. 2013). When light enters an ommatidium, it can pass to the adjacent ones through the wall

of the unit, optimizing the luminous perception and helping in the formation of the image (Fig. 4c).

#### Ocelli

Ocellus ("little eye" in Latin) is a second visual system in addition to the insect's compound eye. It is often found dorsally in a triad (Fig. 3a, b) (but can be from 1 to 3) in different locations on the heads of flying adults of most orders and in immatures of most nonholometabolous orders. While compound eyes are sophisticated visual organs responsible for functions that require good spatial resolution (e.g., motion detection, pattern recognition, and color vision), ocelli are able to detect only changes in light intensity over a wide visual field for having high aperture diopter. Although compound eyes are much more complex organs, precisely because they are simpler, ocelli are superior in terms of photic sensitivity and speed of

**Insect Sensory System, Fig. 4** Compound eye of a hypothetical insect. (a) a single ommatidium of an apposition eye. (b) apposition eye. (c) superposition eye. (Adapted from Chapman et al. (2013))

signal transmission, thus complementing the functions of compound eyes (Mizunami, 1995).

Ocelli consist of a single lens, and beneath, the ocellar receptor cells are arranged differently than in a compound eye. In the compound eye, the receptor cells are arranged in an ordered array with its rhabdoms presented as a mosaic of guides for the passage of light. Whereas in the ocellum, the rhabdoms are arranged as irregularly packed cells forming a network of baffles (Wilson, 1978), probably maximizing their ability to capture light scattered diffusely across the retina (Mizunami, 1995).

### Stemmata

Stemmata are the visual structures of holometabolous larvae, occurring laterally on the head and can vary in number from one (most typically) to six on each side (Chapman et al. 2013) (Fig. 3c, d). Stemmata have been wrongly called lateral ocelli, but they differ in morphology and origin. Studies based on morphology and DNA revealed that stemmata evolved from compound eye ommatidia of hemimetabolous (i.e., type of development where the larvae are morphologically similar to the adult, except for the absence of wings and being sexually immature, in addition to the presence of some larval characteristics such as tracheal gills for aquatic groups) ancestors (Paulus, 1986; Liu & Friedrich, 2004).

These structures are composed of a cuticular lens in the outermost portion, above the lens. Below the lens are retinular cells, which can vary in number and shape. From the arrangement of these cells, a single rhabdom or many rhabdoms can be found, conditions that vary from group to group (for a comprehensive review of stemmata see Gilbert, 1994).

### Dermal Light Sense

Some insects are also able to sense luminosity from photosensitive epidermal cells, or extra-ocular photoreceptor cells. These cells are usually small receptors with a transparent cuticle diffusely distributed in the body surface. Unfortunately, we still know relatively little about this way of sensing light, but Ramirez et al. (2011) made a review about the knowledge about dermal light sense in

animals. Although studies in the area are scarce, it is already known, for example, that some butterflies use a small set of photoreceptors located at the end of their abdomens to control copulation in males and oviposition in females (Arikawa et al. 1997).

## Temperature and Humidity

Sensory cells that respond to temperature and humidity are usually present together in a single sensillum called **thermo-hygroreceptor**. The mechanisms responsible for the ability of insects to respond to humidity and temperature gradients are still poorly understood, but all species that have been studied have sense cells responsive to temperature and humidity on the antenna (Chapman et al. 2013). Sensor cell consists of a short peg bristle without pore and an immovable socket.

While one of the hygroreceptors responds to an increase in humidity (**moist receptor**), the other responds to a decrease in humidity (**dry receptor**). The thermoreceptor responds to a drop in temperature, called the cold receptor. The response rate of these receptors varies according to the insect, but in *Periplaneta* Burmeister, 1838 (order Blattodea), for example, the dry receptor has a higher tonic firing at low humidities than the moist one, being more quickly affected in drier environments. Also, the same receptor is sensitive to temperature, with a higher firing rate at higher temperatures than in lower ones (Chapman et al. 2013).

## Insectivora or Eulipotyphla Locomotion

### ► Insectivore Locomotion

## Insectivore Diet

Heidi Bissell

SeaWorld Parks & Entertainment, Tampa, FL, USA

## Introduction

In 1960, insects were estimated to have a worldwide biomass of 1000 billion metric tons (Williams 1960), but current estimates have lowered that estimate to half that amount – only 500 billion metric tons (Koerth-Baker 2017). This is still an order of magnitude greater than humans (60 billion metric tons) and an quarter of all animal biomass on earth (2000 billion metric tons) (Bar-On et al. 2018).

The diversity of insect species is staggering – over a million species have been identified to date, likely only a small fraction of the total. Insects are found in every ecosystem on earth and in nearly every niche, with every type of life history imaginable – short-lived, long-lived, seasonal, year-round, flying, burrowing, parasitic, social, and more.

*Insectivores*, insect-eating animals, exploit this resource, turning this abundant biomass into their own fuel. (Colloquially, the term “insectivore” is often applied to animals that consume insects as well as other arthropods such as arachnids (spiders and scorpions) and myriapods (centipedes and millipedes.) Insectivorous animals include nearly all amphibians, numerous bird, fish, and rodent species as well as anteaters, armadillos, pangolins, the aardvark, and many insects themselves. Nearly every taxa of animals, though, consumes insects as some part of their diet.

## Being an Insectivore

Insects vary in abundance across both space and time. Many insects have strong seasonal or even multiannual cycles of abundance (e.g., 17-year cicadas). Insectivores must therefore acquire sufficient food to meet their energetic and nutrient needs throughout the year from an ever-rotating set of different insect populations. Specialization in a singular insect species is therefore rare – most insectivores are generalists within a particular niche. For example, pangolins, armadillos, anteaters, and sloth bears are all termite-eaters. However, they may eat from dozens of different species of termites, as well as ants, bees, wasps, and moths living in many different nest types – arboreal nests, dead trees, or elaborate concrete-like mounds. Aerial feeders often fly above bodies of water, consuming whichever insects are hatching at that time of year. Such a diverse diet likely helps balance deficiencies and smooth over temporal differences in insect species' abundance. Many vertebrate species are only seasonally insectivorous, taking advantage of the large booms in insect populations during some seasons, even if they are primarily frugivorous or granivorous the rest of the year. For example, many otherwise herbivorous birds will consume large amounts of insect prey when they are feeding nestlings. Insects form an important part of the reproductive cycle for these species. Still other insectivores may eat insects only occasionally, such as chimpanzees and gorillas, who feed on insects as a small part of their diverse diets. A hallmark of insectivory is flexibility – both evolutionarily in terms of different methods to catch insect prey and behaviorally in terms of different techniques and search patterns.

### Detecting Insects

Insectivores must first find insects. Some use a sit-and-wait strategy, such as a spider waiting in its carefully spun web or the African bullfrog, which waits for its prey to come near before ambushing. Other species may search a general area to locate patches of insects, such as an anteater inspecting a field of termite mounds or a swift circling a lake looking for swarms of midges. Still others actively

search across an area looking for individual insects (such as a frogmouth taking short flights to look for large moths, or chickens pecking in a field) or spend considerable energy breaking into fortified and defended hives (bee-predators such as honey badgers, bears, and giant armadillos) or termite mounds (anteaters, giant armadillos, armadillo, sloth bear).

Depending on the species and the hunting method, all senses may be involved. Aerial predators typically use sight, although some, such as bats, use echolocation to detect their prey. Termite eaters use smell as well as audio and visual cues to find nests. Trout can detect insects visually above the water or use their tactile senses via their “whiskers” to detect an insect or worm in the water. Shrews locate insects using their senses of smell and hearing as their eyesight is poor. Insect insectivores may use all of the above to detect insects.

### Capturing Insects

The methods by which insectivores capture insects are nearly as diverse as the predators or prey themselves. Amphibians capture prey with a projectile thrust of their tongue, calculating their prey's trajectory and timing their movements to coincide with its movement. Anteaters also use their tongue, but instead of a projectile, their tongue acts as a sticky tool able to feel its way around inside the tunnels of a termite nest, extracting the insects within (and often a fair amount of mound material and soil). Praying mantids capture their prey with lightning fast leg movements and use spikes on their legs to hold their prey firmly. Web-building spiders use perhaps the most famous mechanism, spinning an elaborate web of nearly invisible silk and waiting for their prey to become stuck. Spiders may feed immediately or will wrap the prey in silk for a later meal. Aerial insectivores, such as swifts and bats, catch insects in flight, particularly at dawn and dusk when the prey are most abundant.

### Energetics of Insectivory

Successful insectivory requires balancing the nutrients and energy gained from insects with

the costs and risks of acquiring and digesting insects. Several strategies are common among insectivores. Many insectivores have low basal metabolic rates compared to noninsectivorous species (McNab 1986, 2002, 2009). Insectivorous marsupials, bushbabies, lorises, tarsiers, and xenarthrans (anteaters and armadillos) have characteristically low metabolic rates (McNab 1978; Elgar and Harvey 1987; Nagy 2005). Among birds, many insectivorous species exhibit torpor, and even short periods of no consumption can cause drops in core body temperature (McNab 1966; Weathers et al. 1984, 1990). Birds that exhibit torpor are highly likely to be either frugivorous, nectivorous, or insectivorous – in other words, they rely on foods that vary in availability (Hainsworth et al. 1977; Barclay et al. 2001; Schleucher 2004). These low energy adaptations likely help animals survive periods of low insect abundance.

## Insects as Food

### Insect Lifestage

Insects develop through several distinct lifestages, and their nutrient composition changes with their changing body forms. Larval stages tend to be higher in fat while adult insects are typically higher in protein. For example, mealworm larvae contain 49% and 35% protein and fat, respectively, on a dry matter basis, while the adult beetle form contains 65% and 15% protein and fat, respectively (Finke 2002). The more sedentary or nonfeeding a lifestage is, the more likely it is to be high in fat because it must store energy for its next transformation. Waxworm larvae, which do not feed at all, contain only 34% protein but are over 60% fat, while cricket nymphs, which resemble miniature adults, contain nearly double that level of protein (67%), and have only a quarter of the fat (14%; dry matter basis, (Finke 2002)). The amino acid profile of insects is generally very good, often on par with that of vertebrate prey (Bosch et al. 2013, 2014).

### Insect Diet

The insect's diet can also impact its macronutrient composition. For example, cockroaches, black

soldier flies, and mealworms reared on a high protein diet were higher in protein than those reared on low protein diets (cockroaches: 61% vs. 38%, black soldier fly: 46% vs. 39%, mealworms: 51% vs. 44% (Oonincx et al. 2015)). These nutrient changes may be due to direct changes in body composition or simply via the availability of nutrients found in the undigested food in the gut.

Insects also vary in their content of calcium and phosphorus depending on the mineral concentrations in their own diet. Many insects, both wild and commercially raised, are either deficient in calcium or the ratio of calcium: phosphorus is too low to meet vertebrate mineral requirements (Finke 2002, 2012, 2015; Oonincx and van der Poel 2011; Oonincx and Dierenfeld 2012). Vertebrate insectivores likely have mechanisms to cope with this, such as selecting insect types with higher calcium levels or feeding on calcium-rich items such as eggshells, bones, limestone, or clay. They may also have metabolic mechanisms to increase absorption or retention of dietary calcium. For example, tissue calcification has been observed in many tamanduas consuming diets containing amounts of calcium that would be normal for most other mammals (Woc Colburn 2015), indicating that they may retain more calcium than many other species.

### Chitin

The chitinous exoskeleton of insects can function in ways similar to fiber in the diet of herbivores. Many animals, including insectivores, produce endogenous chitinase enzymes, which can break down chitin, releasing energy. For others, chitin may provide necessary substrate for intestinal microflora and thereby support gut health. Giant anteaters, for example, have improved fecal condition on diets supplemented with either commercial chitin supplements or other fibrous compounds such as ground peat (Wyss et al. 2013; Leuchner et al. 2014; Gull et al. 2015).

### Other Nutrients

Outside of the macronutrients, insects cannot be categorized easily as generally “high” or “low” in particular vitamins, fatty acids, or other chemical compounds. Most insectivores will consume a

variety of different insect types to amass the nutrients they need.

Carotenoids (red and orange pigments found in many plants) are consumed by insects, primarily from plants or blue-green algae. Frogs consuming carotenoid-rich prey show improved coloration (Brenes-Soto and Dierenfeld 2014), immunity, and reproductive health (Ogilvy et al. 2012).

The diet can also impact the nutritional value of an insect in a different way – through the gut contents. For captive animals, a common technique used to increase the content of certain nutrients such as calcium, vitamins, or carotenoids is to *gut-load* insect prey by feeding the insects foods high in the target nutrient. Insectivores thereby receive these nutrients when they consume the prey along with its gut contents. Gut contents likely provide key nutrients to wild insectivores as well.

## The Future of Insectivory

Worldwide, insect populations are in decline (Vogel 2017). In Germany, flying insects declined by over 75% over a 10-year period (Hallmann et al. 2017). In England, over 2/3 of the moth species showed reductions over a 35-year period (Conrad et al. 2006). Bees face many threats (NRC Committee on the Status of Pollinators in North America 2007; Fisher et al. 2012; Vanbergen and Initiative 2013), putting large sectors of human agriculture at risk. Population data for other insect species and locations is largely unknown, but anecdotal evidence is that nearly all insects are in steep decline.

Another risk to insectivores is mismatched timing due to the effects of climate change. Insects may hatch out of sync with the foods they eat or the blooming of the flowers they pollinate, risking the populations of both the insect and floral species. Birds may hatch out of sync with insect populations, meaning parents have less food available to offer their growing brood (Roy and Sparks 2000; Schweiger et al. 2008; DeLucia et al. 2012; Renner and Zohner 2018) and may risk malnutrition (Burgess et al. 2018).

On the other hand, insects have high feed:gain ratios, meaning that more edible product

is produced from fewer inputs (DeFoliart 1989; Bernard et al. 1997; Huis et al. 2013; Anankware et al. 2015). This makes them one of the most efficient ways to begin to feed the world's growing human and animal populations.

## Synonyms

Insectivora or Eulipotyphla locomotion; Mole, hedgehog, or shrew locomotion

## Definition

Movement used by solenodons, moles, shrews, and hedgehogs to traverse their environment.

Insectivores are fossorial, terrestrial, and/or semiaquatic mammals. They are generally found worldwide except in Australia, Antarctica, and South America. For years, “*Insectivores*” has been treated as somewhat of a wastebasket taxon and there has been considerable disagreement on the exact composition of the group until genetic analyses established the order Eulipotyphla (D’Agostino 2015). Within Eulipotyphla, the families are *Soricidae* (shrews), *Solenodontidae* (solenodons), *Talpidae* (moles), and *Erinaceidae* (hedgehogs and gymnures). Insectivores comprise nearly 10% of all mammalian species and are quite small in size ( $\leq 1$  kg). Generally, they have soft and dense fur, but some species such as hedgehogs have altered their fur into stiff,

protective spines. Insectivores are useful in aerating soil and controlling vermin as well as insects that damage crops. Most are terrestrial or fossorial, with a few species displaying semi-aquatic behavior or arboreal adaptations. They occupy a wide range of habitats such as sand dunes, tropical rainforests, deserts, and high elevation mountains (Kurta 1995).

## Shrew Locomotion

Shrews (family *Soricidae*) generally have a long cylindrical body with short legs and simple feet (i.e., they have five toes on their forefeet and hind feet). Shrews display a variety of locomotor behaviors including burrowing, climbing, and swimming (Woodman and Wilken 2019). The gait repertoire of a shrew includes walks, trots, and bounds (Moskowitz 2010) (Fig. 1). Walks and trots are classified as symmetrical gaits (i.e., footfalls of forelimbs and hindlimbs are evenly spaced in time), whereas, a bound is an asymmetrical gait (i.e., actions of forelimbs and hindlimbs are unevenly spaced in time). The American water shrew (*Sorex palustris*) is semi-aquatic and exhibits “water-walking” behavior due to its large webbed hind feet with stiff hairs on the sides of each of the toes. Air bubbles become trapped in the fur, allowing the shrew to remain on the surface (Grosvenor 1979).

Shrews often utilize a crouching posture, allowing them to maintain close contact with the ground. However, crouching behaviors come at increased costs during locomotion. Riskin et al. (2016) explored the mechanical cost of crouching in shrews compared to more upright, but similarly sized, voles. Compared with crouching shrews, more upright voles used less positive power to increase the kinetic energy of the body during locomotion, making the total requirement of mechanical power per kg for locomotion smaller. This suggests that the metabolic cost of locomotion is reduced by an upright gait compared with a crouching one. The persistence of crouching in shrews, despite the mechanical advantages of a more upright gait over a crouching one, suggests that some other selective benefits to crouching

**Insectivore Locomotion, Fig. 1** Hildebrand plot showing the relationship between hindlimb duty factor (%) and Phase (%) for two species of insectivores [Blue = European hedgehog (*Erinaceus europaeus*); red = European mole (*Talpa europaea*)]

must exist. Ease of movement through tight burrows and reduced conspicuousness to predators are two obvious ones. Another would be readiness to accelerate quickly, without the need for a pre-jump crouch that would be necessary for an animal standing on outstretched limbs. Furthermore, Fischer (1994) has argued that advantages of crouching include an improved ability to maneuver around unexpected obstructions.

Due to high surface-area to volume ratios and metabolic rates, energy requirements play a major role in the selection of a suitable territory for shrews. Smaller shrews tend to occupy larger and less productive territories than larger individuals (Hanski and Kaikusalo 1989; Saarikko 1989). This may be a result of interference competition, in which larger shrews are able to outcompete smaller individuals in highly productive habitats with a greater variability in food availability. When there is a significant reduction in food availability, larger shrews decrease their activity. In contrast, smaller shrews must compensate by increasing their foraging activity. According to Saarikko (1989), shrews physiologically adapt to colder conditions or a decrease in

food resources by reducing the size of their body and skull to minimize energy use. This is achieved through the breakdown of cartilage and bone near the spine as well as the bones at the joints of the skull.

## Mole Locomotion

Fossorial insectivore species, such as moles (family *Talpidae*) have short forearms that are specialized for digging, and practice a sprawling, rather than upright, stance. The palms of moles contain a falciform bone (“sixth digit”), increasing the surface area of the palm. Enlarged claws on each toe break apart compact soil and larger, paddle-shaped forefeet act as shovels (Kurta 1995). In the forelimb, the trochlea of the humerus limited most pronation or supination, and olecranon process of the ulna is quite large for the attachment of triceps musculature. Together, this enhances its utility for lateral thrust digging, which causes dirt to be pushed away laterally from the body (Barnosky 1982). The humerus is also short, broad, and compact with prominent muscular attachments. This forelimb anatomy assists moles in traveling long distances to search for and transport food. Its clavicle is short and is directly connected to the humerus instead of the acromion, absorbing the stress from lateral thrust digging.

Moles use a symmetrical gait, in which the contralateral hindlimb and forelimb move synchronously with minimal lateral body-roll. Throughout stance phase, the sixth digit remains in front of the shoulder and elbow joints and it is used to move the body forward (Lin et al. 2019). This pattern is similar to a human using a cane or walker. The sixth digit is the only point of contact during locomotion. This suggests that the sixth digit supports the entirety of the mole’s bodyweight.

As burrowers, it is necessary for moles to be able to move and transport various types of soil. Lin et al. (2019) studied a fundamental difference in how moles use their forelimbs to burrow versus other mammalian diggers. Moles move substrates upward or outward from the body midline to

compress it into the side of the tunnel. This contrasts with the traditional method utilized by burrowers that displace substrates directly rearward. While moving through tunnels, their humerus is retracted and protracted in the parasagittal plane above, rather than in or below the horizontal plane. This pattern allows moles to traverse through underground tunnels with their arms sprawled out in front of them, preventing the destruction of their self-built tunnels.

The locomotor mechanics of underground animals, such as moles, can be useful in the development of search and rescue robots in areas that are not readily accessible. Lee et al. (2020) used information gleaned from the locomotor behavior of moles to develop a directional drilling robot. With a linear actuator simulating the mole's scapula, and an excavator mimicking that of the mole's forefoot, the robot would be capable of efficient excavation. Lee et al. (2020) stresses the importance of a device which could drill, clear any associated debris, and traverse within it.

## Hedgehog Locomotion

Hedgehogs (family *Erinaceidae*) have a slow, waddling gait, with the ability to accelerate to high speeds for brief periods of time (Quesenberry and Carpenter 2011). They have a distally fused tibia and fibula, as well as five digits on their forefeet and four digits on their hind feet. Their back is covered by spines, composed of keratin and modified hairs, which serve as a protective mechanism from predators. Hedgehogs utilize a lateral-sequence diagonal-couplet walking gait (i.e., each hindlimb footfall occurs before that of ipsilateral forelimb, with simultaneous movement of contralateral forelimb and hindlimb) (Granatosky 2019; Villanova et al. 2000). This gait provides enhanced stability for walking when the body is supported by two or three legs and prevents a lateral-body roll. At moderate speeds, hedgehogs are also capable of a trotting gait (i.e., symmetrical running) in which contralateral forelimbs and hindlimbs move together simultaneously. When moving at higher speeds, the limbs are extended to raise the body above the

ground (Rondinini and Doncaster 2002). Its fossorial ability is indicated by the brachial fossa being positioned in front of the greater tubercle on the anterior portion of the humerus and a clavicle that attaches to the acromion process of the scapula and to the manubrium. These features of the forelimb limit the motion of the shoulder in the anteroposterior plane (Goodarzi 2018; Hashemi et al. 2009).

Hedgehogs have done remarkably well in urban areas. In fact, many urban areas in Britain have higher hedgehog populations than the surrounding countryside. Likely, this is attributable to a greater abundance of food resources and lower incidence of predators. Pettett et al. (2017) demonstrated that as European hedgehogs (*Erinaceus europaeus*) move further away from buildings daily energy expenditure increases, possibly as they ranged larger distances on arable land. This suggests that hedgehogs select villages owing to the lower energy demands in comparison to arable farmland. Additionally, the presence of predators (i.e., badgers) also influences daily energy expenditure (hedgehogs show approximately 30% lower daily energy expenditure on sites with badgers). Pettett et al. (2017) speculate that on badger-occupied sites, hedgehogs may restrict movement and foraging in response to a threat from predation and thus have reduced daily energy expenditure. Therefore, hedgehogs may also seek refuge in villages where the perceived threat of predation is lower, and foraging is unrestricted. However, Patrick et al. (2008) demonstrated that within urban areas hedgehogs are attracted to linear features (i.e., roads). In such settings, hedgehogs are often involved in motor vehicle collisions, rendering roads as a barrier to movement.

## Conclusion

This chapter discusses the wide range of locomotor behaviors displayed by insectivores. Largely plantigrade, insectivores utilize symmetrical walking gaits. Exceptions to this include the American water shrew (*S. palustris*) that displays a "water-walking" behavior. Shrews also are able

to climb, burrow, and swim, with a wide gait repertoire that includes walks, trots, and bounds. The unique limb morphology of moles enhances the utility of lateral thrust digging, while allowing them to traverse through tight spaces without collapsing their self-built tunnels. Hedgehogs, identified by the coarse spines overlying their backs and sides, exhibit a slow waddling gait with the propensity to trot in short bursts. Insectivores also display unique behaviors and adaptations in response to environmental changes. Shrews, for example, are able to shrink their body and skull size through remodeling of cartilage. Hedgehogs, on the other hand, are often found in urban areas and are attracted to linear features, such as roads, which may predispose them to accidental road deaths. Future applications of insectivore locomotion include the creation of a directional drilling robot model, based on mole locomotion, which can potentially navigate difficult terrains and diffuse land mines.

## Insight

Juan-Carlos Gómez  
School of Psychology and Neuroscience,  
University of St. Andrews, St. Andrews, UK

## Synonyms

“a-ha moment”; Apprehension of relations;  
Eureka effect; Ideational behavior

## Definition

Insight refers to a family of phenomena related to problem-solving and understanding. In humans these typically involve the sudden realization of how to solve a problem that previously resisted resolution and, in animals, the sudden execution of a solution where previously there was failure, with discontinuity between the inappropriate and the correct behavior. There are considerable ambiguity and variation in the use of the term by different authors, sometimes referring to a type of behavior – sudden innovative solutions – other times to the subjective experience of understanding the problem and its solution, and other times to the hypothetical cognitive mechanisms underlying the observable behaviors and subjective experiences. This variety in definition (which, to complicate things, frequently is not made explicit) may explain some of the unresolved debates around the notion of insight within comparative psychology, both historical and contemporary. Although initially described in primates, insight has been attributed to a variety of avian and mammal species.

## Origins of the Notion of Insight: Köhler on Chimpanzee Problem-Solving

The Gestalt psychologist Wolfgang Köhler (1917/1921) formally introduced and popularized the term “insight” in psychology when reporting the results of his pioneering experiments on chimpanzee problem-solving. The apes – he claimed – acted not with blind trial and error but with “insight” [*Einsicht*]. In this original use, Köhler did not intend to coin a new technical term, but to use it as a synonym of “intelligence” or “understanding” in the common sense of these words (indeed the original title of the book known in English as *The Mentality of Apes* was *Tests of Intelligence on Anthropoid Apes*). His key finding was that chimpanzees confronted with problems (an obstacle preventing them from achieving a goal) responded with behaviors resembling what we call “intelligent” in ordinary language – finding an indirect way to overcome the obstacle. For

example, the apes used sticks to get food that they could not reach directly with their hands or moved boxes under a hanging fruit that they could not grasp from the floor.

The term “insight” came to identify the opposite of trial and error. E.L. Thorndike’s (1898/1910) earlier influential work on animal intelligence reported that cats trying to get out of a puzzle box learned the solution (pushing a lever) only through slow, prolonged trial and error learning – “a gradual elimination of unsuccessful movements, and a gradual reinforcement of the successful one” – which came to be known as the “law of effect.” Köhler argued that Thorndike’s tests had a key flaw – the mechanisms of the puzzle boxes were not visible to the cats, and therefore, they were in no position to demonstrate any understanding of them. For his chimpanzees, Köhler chose tests whose conditions (target, obstacles, and any relevant elements) were fully visible, and he used a wide variety of tasks ranging from easy (e.g., approaching the goal through a roundabout or using one stick) to very difficult (e.g., combining sticks or moving the goal in a projected roundabout; see later).

Under these conditions, the apes produced sudden solutions preadapted to the structure of the problem without having to go through blind trial and error. Although in a given problem the chimpanzees might at first engage in unsuccessful attempts (e.g., trying to directly reach the goal with their arms), they abruptly changed their approach executing correct solutions in a smooth, continuous way. Köhler concluded that the chimps showed “intelligence or insight of the human type.” Even when failing problems, they frequently made “good errors” reflecting a “partial insight” of the situation, for example, trying to lift a door over a stone blocking its path, instead of removing the stone, or piling boxes to build a higher tower, but without attending to the visual statistics to optimize box balancing.

In his first use of the term “insight,” therefore, Köhler intended it to be synonymous with “intelligence” or “understanding.” He did not initially propose a specific theory of intelligence or insight, although he suggested this would come from within the nascent school of Gestalt psychology.

In later elaborations, Gestalt psychologists used insight in a more general, potentially explanatory sense – the ability to “apprehend the relations” between the elements of a situation, which in problem situations would require a restructuring to lead to a solution. This apprehension of relations included not only the perceptual field but also the subjects’ actions and previous experiences, which were part of the field of relations that needed restructuring to solve the problem.

Other Gestalt psychologists (e.g., Duncker 1935) adopted the term insight to investigate problem-solving in humans. In this area, the term is associated not only to the production of sudden innovative solutions but also to the subjective “a-ha experience” – the feeling of clearly and suddenly “seeing” and understanding the solution to the problem. Insightful problem-solving has continued to be the object of intensive research in human cognitive psychology and neuroscience (Bowden et al. 2005) with some conceptual and methodological issues overlapping with comparative psychology.

One recurrent problem in animal psychology is to what extent and in what sense animals experience a representational “understanding” of the problem and its solution before executing the latter and how this could be investigated.

## Definitions of Insight

In comparative psychology, definitions of insight make reference to the novel and sudden nature of the behavior that resolves a problem. One of the most widely used definitions is W. H. Thorpe’s (1956), who distinguished between “insight” as the “apprehension of relations” in perception and “insight learning” as “the sudden production of a new adaptive response not arrived at by trial behavior, or the solution of a problem by the sudden adaptive reorganisation of experience” (Thorpe 1956, p. 100). Although a definition in terms of suddenness and novelty of behavior could appear to be objective, in fact it is difficult to specify precisely what counts as “sudden” and “novel.” How different from previous experience and existing behaviors should an insightful

solution be? How discontinuous its emergence? Is it necessary that there is a previous impasse with unsuccessful attempts?

The definition of insight is further complicated when reference is made to specific mechanisms or unobservable experiences, as Thorpe does in the second part of his definition. How can we tell if there has been a “reorganization of experience,” other than by the production of the novel behaviors mentioned in the first part of the definition?

Other authors propose that insight requires that the novel behaviors are based upon a causal understanding of the structure of the problem and how the solution works, while others emphasize the need for “mental planning,” where the steps of the solution are mentally represented before their execution. What counts as causal understanding? How much causal understanding is necessary – should every component of the solution be causally represented? Should all steps be represented in advance, and in how much detail? We will discuss examples of these later.

Thus, although insight seems to be an intuitive concept, in practice from its inception, it has remained difficult to define and operationalize with precise criteria (Hartmann 1933; Shettleworth 2012). One recurrent debate is if insight is an expression of general cognitive mechanisms or it involves unique, specific mechanisms that set it apart from other manifestations of intelligence. Within learning theory, the question is if insight is a special type of learning or a manifestation of general learning principles.

## Insight and Behaviorism

In the years following Köhler’s publications, insight became a challenge for the increasingly dominant (not only in comparative but also in psychology in general) paradigm of behaviorism. In America the notion had been further popularized through the work of Yerkes (1916), who had reported insightful behaviors in an orangutan at the same time as Köhler. Although he initially referred to this as “ideational behavior,” he eventually adopted Köhler’s term. Behaviorist

psychologists attempted to provide accounts of insight from inside behaviorist theory.

For example, Harlow (1949) proposed that it was a manifestation of “learning set,” the progressive facilitation in the acquisition of new responses based on previous experience with similar situations (“learning to learn”). In Harlow’s arbitrary discrimination tests, initially monkeys needed many repeated trials to acquire by trial and error the correct discrimination. As the number of discrimination tasks learned by the monkeys increased, the time to discover the correct option progressively diminished until, after 200 problems, they could discover the correct option of new problems by the second trial (the first trial always remained 50%, as the correct choice was arbitrary). Harlow argued that this transition from chance to perfect performance in just one trial was a case of insight, but one that was clearly dependent upon a previous, extended and progressive sequence of associative learning. He suggested that, in standard insight problems, animals must produce their sudden solutions relying on some unrecorded previous experience of this type. It is, however, contentious that Harlow’s discrimination problems, where the correct choice is always arbitrary, are equivalent to traditional insight problems, where the structure of the situation is transparent and the correct solution is in principle achievable from trial one. The relevance of the notion of learning set for understanding insight remains, therefore, doubtful.

Schiller (1952) proposed that the tool using patterns exhibited by chimpanzees (e.g., stick use and box displacement) were in fact “instinctive” action patterns that may have become associated with the appropriate situations by trial and error. He observed that, when provided with sticks and boxes outside a problem-solving situation, chimpanzees playfully produce the behaviors needed to solve Köhler’s problems. For example, they drag the boxes around, climb on them, and jump from them with outstretched arms. He suggested that when placed in a problem-solving context (e.g., a banana hanging from the ceiling), it would be a matter of time until by chance they produced the “appropriate” behavior, either already in their repertoire or highly likely to emerge “by instinct.”

Within behaviorism, therefore, some authors resolutely sought to demonstrate that insightful behaviors were fully explainable from the general principles of associative learning. Other authors tried to account for insight through more sophisticated versions of behaviorism with more complex notions than basic stimulus-response associations (e.g., Tolman's (1932) purposive behaviorism and his studies of insight in rats learning mazes). Hebb (1949) argued that an important effect of the notion of insight in America was to discard "naïve" associative theories of trial and error learning, forcing behavior theorists to develop more sophisticated accounts of learning to try to accommodate insightful behaviors.

### Insight as Practical Intelligence

Many developmental psychologists adapted Köhler's tasks as tests of practical intelligence for infants and children. The most important contribution came from the Swiss psychologist Jean Piaget (1936), who incorporated insight into his theory of practical or sensorimotor intelligence, arguing that, in human infants, innovative solutions without overt groping are first produced during the final stage of sensorimotor intelligence (18–24 months) through "mental groping" with interiorized actions or "the invention of new means through mental combinations." For Piaget, insightful solutions were in strict continuity with prior stages in the development of practical intelligence (means-ends coordinations of known schemas at 8–12 months; creation of new adapted schemas through overt directed groping at 12–18 months). Groping here is not *blind* trial and error (if anything, this occurs during stage 3 of sensorimotor intelligence, at 4–8 months of age, when infants repeat actions that provoke interesting effects without attending to their causal connections) but active or goal-directed experimentation. In insight, this experimentation occurs internally in the mind of the child.

Piaget saw insight as one more manifestation of the constructive development of the sensorimotor

system of intelligence and criticized Gestalt psychology for implying that such reorganizations could be the result of innate laws of form ingrained in the nervous system.

### Blind Versus Insightful Trial and Error

Insight is traditionally contrasted with trial and error (T&E) learning. However, both may not be mutually exclusive. As pointed out by Piaget, T&E can be "intelligent" or goal-directed. Moreover, even in blind T&E (with actions randomly generated), errors may become a source of insight, helping the animal understand what is the correct approach. This would amount to having a retrospective insight. A common phenomenon in human experience is indeed to discover an effect by chance and then realize why it works by examining the structure of the situation. For example, I might discover by chance, after several blind trials, how to unfold a chair and realize why this particular pulling movement works and from then on keep the movement, not just because it worked once but because I now know how it works.

Something similar might happen in animals. One of the more difficult problems faced by Köhler's chimpanzees was the "projected roundabouts" task, where the by then well-practiced schema of dragging objects to oneself with a stick no longer works because an elevated U-shaped screen prevents the animals from reaching the raked in target. The solution is to push the target away from themselves until it can be moved sideways out of the U-trap and raked as usual to themselves. Most apes struggled with this problem. They raked the object to themselves, sometimes trying to lift it with the stick against the screen. One of the chimpanzees benefitted from a chance solution – he pushed the target so forcibly against the screen that it rebounded in the correct direction away from the trap. This happy accident prompted him to produce the correct solution for the first time (pushing away instead of pulling). He still needed a few more such happy accidents to start with the correct pushing movement in subsequent trials. This example suggests

the possibility of insightful T&A where a chance occurrence helps lead to a correct solution (pushing away), which fundamentally differs from the action that led to the happy accident (pulling). Insightful T&A in animals needs systematic investigation.

## Insight and Experience

A common misconception of insight is that sudden innovative solutions must not depend upon any previous experience and that any demonstration of an effect of experience would discount them as insight.

However, in the original conception by Köhler and later elaborations like Piaget's, experience plays a key role in insight. What matters is that this experience (existing behaviors) is not by pure trial and error, and its reorganization is not reduced to a mere generalization of previous responses. There must be a generation of new solutions, but these inevitably build upon previous experience with the relevant materials and situations. An excellent example, both of the misunderstanding and how experience may operate in problem-solving, comes from Birch (1945), who in a carefully controlled experiment demonstrated that, with no previous experience with sticklike objects, chimpanzees were unable to produce the behavior of raking in out-of-reach targets. After only 2–3 days of experience with natural sticks, the chimps were able to produce the raking solutions. However, during their free exploration of the sticks, they produced only poking and stabbing behaviors, no dragging actions. It was only when confronted again with out-of-reach targets and rakes that they immediately produced for the first time correct raking actions. Thus, on the one hand, *some* experience with the relevant material was necessary, but this did not provide the movements required for the solution – these emerged only when confronted with the problem situation. Although sometimes this study is quoted as evidence against insight, it in fact may fit well the original accounts of insight as restructuring of existing experience and schemas.

## Training Insight: A Behavior Analysis Recipe

Behavior analysis studies conducted in the 1970s showed that, if pigeons are painstakingly pre-trained in the separate components of a solution, ensuring that the necessary actions and responses are firmly established in their repertoire, they may spontaneously produce a novel combination without any specific training for this. Epstein et al. (1984) trained pigeons to step upon a box fixed under a hanging target to peck the target and win a reward. Separately, the pigeons were trained to move a box to particular floor locations marked with green circles to receive rewards. Both actions were separately trained through a prolonged process of gradual shaping. Once these responses were solidly established, the birds were placed in a novel test situation, where the box was away from the hanging target. Initially the pigeons acted “confused,” moving to and fro under the target and looking at the box. Then they started to “rather suddenly” push the box toward the hanging target, adjusting its position until they could climb on it, peck the target, and receive the reward. Interestingly, pigeons trained to push boxes randomly, not to a target, were not able to produce the solution. The “insight” effect happened only if the two components had been firmly pre-established, and the box pushing behavior was target-directed.

Epstein explained the pigeons' behavior strictly with behavior analysis concepts, such as conflict between controlling stimuli, functional generalization, and spontaneous chaining. He suggested that similar learning processes may explain the insightful behaviors observed in chimpanzees and humans, who – he assumed – acquire on their own the behavior components that had to be so painstakingly trained in the pigeons. Epstein's analysis, therefore, did not aim to explain away animal insight, but rather to provide a behavior analysis framework to explain creative and generative behaviors in both animals and humans, including insight.

This approach has some problems. For one thing, insight here is narrowly defined as a novel

combination of fully existing behaviors, rather than the generation of new behaviors. In Piagetian theory, the production of new combinations of existing schemas corresponds to a less complex level of practical intelligence (appearing at 8–12 months), whereas more sophisticated explorative groping and insight develop later (second year of life) and are characterized by the creation of new behavior patterns adapted to novel situations. For example, in Birch's (1945) chimpanzee studies, the key innovation consisted of the creation of the dragging movement with a rake, not just a new combination of existing patterns. A second problem with Epstein's analysis is the assumption that apes' exploratory play would be equivalent to strict goal-directed training. The apes' spontaneous playful behaviors with boxes or sticks may in fact be more comparable to the pigeons that just got rewarded for moving objects around and who failed to show "insight."

### **Spontaneous Avian Insight: The Mentality of Corvids**

In recent years, several studies have reported spontaneous insightful behavior in birds without the need of programmed training and shaping. For example, Bird and Emery (2009) reported that captive rooks – a corvid species that does not use tools in the wild – show insightful problem-solving with a variety of tools and situations. Among other achievements, they selected stones of appropriate sizes to insert through an aperture to make a platform collapse and access rewards. They correctly chose stones even when out of sight of the apparatus, which suggests representational and planning ability. They flexibly used sticks instead of stones, when these were not available, and they modified nonfunctional tools to make them functional, such as bending a wire to create a hook, an ability also found in New Caledonian crows.

Ravens, crows, and keas insightfully solve string-pulling problems to gain access to the food attached to a hanging rope (Heinrich and Bugnyar 2005). From the beginning, they systematically pull the rope up while holding with their

foot the loop after each pull, so that it does not fall back while preparing to perform another pull. If the rope is hanging above them in a pulley disposition, they change at once the pulling direction. This is interpreted as evidence of insight and causal understanding in several Avian species.

As in the 1940s to 1950s with nonhuman primates, these claims have attracted criticism and alternative explanations. For example, Taylor et al. (2012) suggested that string-pulling birds may just apply a familiar food catching pattern – peak pulling combined with foot holding – which is immediately reinforced by the sight of the approaching food. The birds repeat the rewarded movement until they get the food itself, without understanding the causal connection between rope and food. They found that, if the rope was placed in a horizontal position and not fully stretched, when the first pulls failed to produce the rewarding view of the approaching food, the crows stopped pulling without anticipating how the strategy would eventually lead to success. They concluded that the birds lacked the ability to mentally plan the solution with a causal representation of the task. Rather than displaying insight, the birds must have learned this behavior by operant conditioning – the view of the food moving closer acting as an "internal mental reinforcement" that makes them repeat the pull-step sequence until getting the food.

This, however, may fail to explain why the birds applied the pull-step actions to ropes, instead of food, in the first place. Moreover, reliance upon perceptual feedback in the execution of a solution need not be inconsistent with insight, if the solution is pre-adjusted to the perceived conditions. For example, using a stick to retrieve an out-of-reach object without feedback (not seeing the stick, the target, and its reaction to contact) may be difficult for reasons other than understanding their causal connection. In rope pulling, the birds may see the rope as connected to the food and anticipate that pulling should move the food to them, but they may not understand the details of the connection (e.g., the need for the rope to be tight and continuous, providing an uninterrupted connection to the food). That the lack of effect of the first pulls makes them abandon the strategy

could indicate limited causal understanding, but not necessarily a dependence on blind associative reactions.

## Insight Mechanisms: Causality and Planning

The Avian string-pulling debate further exemplifies a definitional issue affecting insight from its inception – should insight be defined by reference to specific mechanisms responsible for the solution (in this case, appropriate causal understanding and representational planning)? The insight debate in recent comparative psychology has indeed merged with the wider, closely related problem of whether animals understand the causal structure of the world. Povinelli (2000) revisited and extended Köhler's classical studies concluding that the amount and nature of failures displayed by chimpanzees should be interpreted as indicative of lack of true causal understanding in apes. This, for him, requires explicit representations of unobservables, such as abstract notions of force or gravity dissociable from the perception of superficial contact or weight. This claim has been contested by other authors reporting evidence that nonhuman primates do not confuse superficial illusions of continuity but correctly use actual functional connections when solving string or support problems. This is consistent with findings that apes are in general not good at learning responses from arbitrary cues in physical tasks (Albiach-Serrano et al. 2015; Mayer et al. 2014).

A “hyper-representational” approach to causality creates the problem of how to probe experimentally the representation of unobservables as distinct from their perceptual cues (e.g., perceptual continuity from causal connection; weight from gravity). For example, Neilands et al. (2016) found that crows did not choose stones of the correct weight to drop on a collapsible platform to obtain rewards, concluding that they lack a causal conception of “force” as separate from “contact.” However, had the crows passed this test choosing heavy enough stones, it could still be argued that they are using the perception of weight

as a concrete correlate of force, and therefore, the test would always fail to demonstrate the alleged representation of unobservables.

A second cognitive mechanism proposed to underlie insight is mental planning or anticipatory representation of the response to be executed. Taylor et al. (2012) argued that the interruption of rope pulling by crows when they could not see the effect of the action showed lack of mental planning. If their behavior was guided by a mental representation of the solution, they should keep pulling without immediate perceptual feedback. However, from this “hyper-mental-planning” perspective, it remains unclear how complete and detailed plans must be to count as insightful. Rather than complete detailed plans, animals (and humans) may produce mental “sketches” of the type “use the stick to contact and drag the food”, leaving open to negotiate with the target the exact type of contact and movement needed in response to perceptual/action feedback. The need for feedback in particular segments of the solution should not make solutions less insightful in the classical sense. A more useful definition of planning could be based upon a notion of mental “sketch” with degrees of freedom to be determined during the execution of the solution itself.

Stipulations of deep causal understanding and full mental planning may depart from the original conception of insight as an expression of practical intelligence linked to dynamic perceptual and action systems and manifest not only in complete, successful solutions but also in “good errors.” A way of integrating these approaches may be through the distinction between implicit and explicit knowledge, with abstract notions of unobservables linked to the latter and schemas of perceptual-motor integration to the former. Importantly, these schemas may embody practical or implicit notions of object, space, or causality. It must be noted, however, that the notions of implicit knowledge and understanding, although widely invoked in psychology and cognitive science, remain themselves poorly defined (Gómez et al. 2017).

Insight may offer a unique opportunity to explore the nature and interplay of explicit and implicit systems of knowledge, as it appears to

occupy a curious position in this characterization. On the one hand, in humans, the process that leads to an insightful solution is opaque to consciousness – the solution just appears to us. On the other, we have a distinct and clear awareness of the solution and why it is going to work, which is very different to a solution found by trial and error, where we know that it works only after seeing the result.

## Conclusion

In sum, insight is a seminal notion that has generated a wealth of research in comparative psychology and other disciplines. It is polysemic, in that the term is used to refer to related, but not entirely equivalent, phenomena (e.g., innovative solutions at the objective behavioral level, the subjective experience of finding a solution at the phenomenological level, or the causal understanding and planning mediating the solution at the level of mechanisms). It is conceptually provocative but also confusing. It is related to key theoretical issues such as notions of implicit knowledge and practical intelligence, but has never been conceptually clarified in its different meanings. More than 60 years after Thorpe's (1956) thoughtful and influential reflections on insight, we can still conclude with him that, although "substantial progress" continues to be made, we still lack a "generally agreed conclusion" about what insight is. However, the notion is still used because it seems to fill a conceptual gap – pointing to something fundamental about the nature of intelligence and understanding that other notions seem to miss.

## Synonyms

Aha moment; Eureka effect; Intuition; Understanding

## Definition

Insight is a spontaneous, continuous, and direct way of solving a problem, also known as the eureka effect or Aha moment. In pigeons, Epstein et al. (1984) defined insight as the spontaneous interconnection of repertoires of behavior.

## Introduction

Sultan, one of the chimpanzees (*Pan troglodytes troglodytes*) of the experiments carried out by Köhler in 1914, was the first ape to solve some of the problems he tested. One of them consisted of reaching a banana after stacking up boxes,

without any specific training. Sultan solved it in a spontaneous, continuous, and direct way. Köhler came up with the German word “Einsicht” to define this way of solving problems; it was translated in English as insight in his book *The Mentality of Apes* (Köhler 1925).

According to Hartmann (1935), the term insight was already used in English colloquially, as a synonym for understanding and, occasionally, intuition. In psychiatry and social psychology, the term is understood as a personality trait that included awareness of the condition of oneself or one’s state (Marková 2005). The Berlin school of Gestalt defined insight as “an understanding of the innermost nature of the field, the stresses not merely apprehended but comprehended” (Hartmann 1935, p. 189), and the explanation of insight given by Köhler was a perceptual restructuring of the field that it was seen as a goal-directed jump in learning, as opposed to gradual learning (Köhler 1925). Nevertheless, the term used to refer to the phenomenon of insight as originally reported by Köhler was changing during the past century, as it was also associated with processes related to intelligent behavior, such as reasoning (Maier 1931) or means-end understanding (Cook and Fowler 2014). Currently, in the Cambridge Dictionary (2019), its definition is “a clear, deep, and sometimes sudden understanding of a complicated problem or situation.”

The insight perspective of learning generated a great debate in the last century, both in experimental and comparative psychology that still has not been solved. The discussion is about the causal explanation of the appearance of new behaviors to solve a problem, due to the conception of the influence of planning-mental learning as a factor in the problem solution as opposed to trial-and-error learning (Hanus 2016). The problem is that the nature of the planning in which nonhuman animals engage is far from clear, so it could be challenging to distinguish from a trial-and-error solution.

Planning should include means-end behavior to represent the insight phenomena because it is said to involve the deliberate, planned execution of a sequence of steps to achieve a goal in

situations where an obstacle must be removed to reach it (Piaget 1954), but sometimes it can also be driven by physical knowledge. This knowledge is not based on abstract and unobservable object properties but on first-order perceptual information like visual feedback. Seed et al. (2011) explained that, in this case, “abstract means that the information is not equivalent or reducible to concrete, analogue sensory input, but rather has undergone further processing in which meaning is extracted” (p. 2). For example, in different problem tasks where the reward is out of reach, the approximation of the reward to the subject can have a reinforcement effect that finally leads to the solution of the problem. Thus, associative mechanisms and trial and error appear to explain the solution to the problem (Jacobs and Osvath 2015; Taylor et al. 2012).

The importance of perceptual feedback as well as other possible variables in the emergence of insight is very much debated currently (see Krasheninnikova 2018), so there is a need for additional research. In this way, we could assess the factors that affect the acquisition of problem-solving and planning skills, the flexibility and complexity of such abilities, and the manner in which these skills are limited (Kuczaj and Walker 2012).

Nevertheless, findings of insight have been reported in humans (Wertheimer 1982), non-human primates (Herrmann et al. 2008; Neves-Filho et al. 2014), corvids (Taylor et al. 2010; von Bayern et al. 2009), elephants (Foerder et al. 2011), pigeons (Cook and Fowler 2014; Epstein et al. 1984; Epstein 1985, 1987; Luciano 1991), and rats (Neves-Filho et al. 2015).

In primates and corvids, the spontaneous problem-solving has been explained as a mental trial-and-error process, in which the animals could plan the solution before the behavioral execution (Taylor et al. 2012; Tomasello and Call 1997). The study of insight in pigeons began in 1979 when Skinner, Epstein, and Lanza worked on a series of experiments called the Columban Simulation Project. The objective of the project was to demonstrate the effect of experience on the emergence of complex behaviors generally attributed to cognitive processes in humans, so they explained

the insight emphasizing behavioral phenomena, rather than mental processes (Epstein et al. 1984).

## The Generativity Theory

Epstein et al. (1984) reproduced in the laboratory, with pigeons as subjects, the sudden performance of Sultan in Köhler’s task of reaching the banana. This problem was named the single-box displacement test (Cook and Fowler 2014) and consisted of reaching a plastic banana fixed on the roof of the experimental chamber, without jumping or flying. To solve the problem, the pigeons had to push a box in the direction of the banana, to climb the box, and to peck the banana. The main objective was to establish the effect of specific previous learning in the emergence of a spontaneous solution to a problem.

In the 1984 experiment, Epstein et al. used 11 male pigeons at 80% of their ad libitum weight. They used a feeder located on the floor of the chamber to train two prerequisite behaviors. The responses required to solve the problem, also called prerequisite behaviors, were trained independently. One behavior was trained until the subject achieved an acquisition criterion, and then the second one was trained. One prerequisite behavior was directed pushing that required pushing a box toward a green dot, of 4 cm in diameter, in a position assigned randomly along the wall of the experimental chamber. Pushing responses were extinguished in the absence of the green dot. The plastic banana was not present in these training sessions. Another behavior was to climb the box and peck the plastic banana; other responses that could reach the banana like flying and jumping were extinguished. The box remained fixed on the floor of the chamber, below the banana. Pushing the box had no consequences during the training of this response. The position of the box and the banana was randomized for each training session. Nevertheless, the conditions and amount of training were different among groups.

The experimental group was trained in both behaviors. Four other control groups were trained differently: one group was trained to climb, to

peck the banana, and to push the box but without the green dot; the second group was trained only to peck the banana, the third group was trained only to climb the box; and the fourth group was trained to do both behaviors, but without extinction of other ways to reach the banana, like flying or jumping.

After training, the pigeons were tested for 10 min. The test was carried out in the same experimental chambers of the training sessions of the prerequisite behaviors. In the test, the plastic banana was suspended at a random position in the chamber edge and the box placed in the opposite side. At the beginning of the test, the pigeons of the experimental group directed their behavior to the banana and the box, stretching their necks toward the banana and climbing into the box. After this initial moment, or state of confusion, they began to push the box toward the banana and stopped pushing the box as soon as it was near the banana when, immediately, they climbed into the box and pecked the banana. This performance was named by Epstein et al. (1984) insight or spontaneous interconnection of behavior repertoires. The pigeons with training in one behavior, or without training to push the box toward a goal, did not solve the problem. Thus, pigeons interconnected different behaviors devising a new sequence to solve the problem when they were competent in each response.

Epstein identified some principles about how, under new circumstances, behavior is generated. He described the spontaneous solutions found in pigeons moment by moment in his Generativity Theory (Epstein 1990) dividing the process into four phases: (1) apparent confusion, caused by *stimulus matching* because the test situation had two stimuli, box and banana, that control two different behaviors; (2) first push to the box, in the competition between the two behaviors, the actions directed to the box should win the competition because jumping and flying to the banana were extinguished; (3) to push the box toward the banana is due to *functional generalization* (Bruner et al. 1956), the transference of the function of the green dot to the banana; and (4) cessation of pushing right under the banana, through an *automatic chaining*, because pigeon's own behavior of

pushing produces the stimulus (to be under the banana) that was controlling the other prerequisite behavior, to climb and peck.

In another study, Epstein (1985) investigated whether solving the problem would be more difficult if the number of prerequisites trained was increased. One male pigeon deprived of food and maintained at 90% of the weight ad libitum was the subject. The equipment employed was similar to that of Epstein et al. (1984). The pigeon was trained in three behaviors: (a) to climb a box, (b) to push the box toward a green spot, and (c) to peck a banana. So, the main difference between this experiment and the previous one was the division of the behavior of climbing the box and pecking the banana into two behaviors. In the test, the overall performance was similar to successful performances reported in Epstein et al. (1984) as the period of confusion and the appearance of the solution in the same time interval (1 min approximately), but the performance did not seem to be especially insightful, that is, in a spontaneous, smooth, and directed way. In this performance, there was little evidence of sighting to the banana while pushing the box or even when the box was under the banana. In addition, the pigeon did not climb as soon as the box reached the banana just as it did not peck as soon as it climbed on the box, but nearly 10 s elapsed between both. Notwithstanding, Epstein claims that neither was a trial-and-error performance, because the pigeon kept the box close to the banana before climbing and pecking so the banana would have acquired some control.

Finally, Epstein (1987) expanded the prerequisites trained to four independent repertoires necessary to the solution of a still more complicated problem: (a) to open a door 18 cm high, (b) to push a box toward a green spot, (c) to climb onto a box, and (d) to peck a banana. He used one adult male maintained at 80% of the ad libitum weight. The pigeon had to open the door to access the box, push and climb on it, and peck the banana. In the test, it was also presented a period of confusion but it solved the problem in approximately 4 min. In this case, the solution was not smooth, but Epstein (1987) did not discuss whether he found insight; instead, he argued that multiple

controlling stimuli were interacting in the pigeon's performance creating a more complex situation. He explained the importance of the disposition of the stimuli during the test, because they had never before been combined in this way, only independently during the training of each behavior. So, when multiple stimuli were presented at the same time in the test, it can generate an increase in the competition between behaviors because of all of them are discriminative due to reinforcement history and are controlling the behavior. The subject must decide what behavior to do first and what later. Epstein (1991) concluded that operant behavior is generative and that mechanisms of variation should be investigated more thoroughly along with the elaboration of the principles that predict the transformation of previously established behavior under new circumstances.

Luciano (1991) replicated the single-box displacement test in pigeons doing variations in the type of training of prerequisite behaviors with the objective to identify the stimulus that would control directional pushing behavior in the test. She divided four pigeons into two groups and exposed them to the test. In this case, three behaviors were trained, rather than two, dividing the task of climbing and pecking in two parts. Both groups were equally trained in climbing and pecking tasks. In the pushing task, however, while one group learned the task pushing toward the green spot, the other group learned to push in the opposite direction of the spot. So, this second group, or opposite group, learned the behavior with a different goal, to push the box away of the green spot. In the test, a pigeon from the opposite group, pushed the box in the opposite direction of the banana, and the other one did not push the box at all. Both pigeons trained to push toward the spot suddenly solved the problem, showing insight. Luciano's observations suggest that specific training modified the performance in the final test, even if this training was not functional for solving the problem presented, the directional pushing behavior was influenced in the same direction as was the training. Luciano highlighted the relevance of training for the emergence of insight because it could provide

the functional properties to the stimuli that acquired control over the behavior.

## Means-End Reasoning in Pigeons

Cook and Fowler (2014) tested a two-box displacement procedure to investigate the pigeon's understanding of the means-end properties, or affordances, of the stimuli toward reaching the target. Two male pigeons maintained at 80–85% of their free-feeding weight were trained to move two boxes toward a goal within the arena. Pigeon 1 replicated Epstein's single-box displacement test. It was trained to push a wooden box and tested in the single-box displacement. Then, after three training sessions with a red box, it was tested in the novel box displacement that consisted in standing on a novel box of the same dimensions and weight, but painted red, to peck at the banana. It was successful, yet slower when tested with the novel red box. The authors explained that this behavior emerged from the generalization of goal-directed behavior established with the similar wooden box and its history of appearing in different locations but also can be considered in a means-end account as the pigeon had a concept of "box" and its potential functional application or affordance for solving the displacement problem.

The two-box displacement test consisted of the introduction of two new boxes in the training and testing. Both boxes were blue and with identical dimensions. The first box was functional, as its design allowed standing in order to reach the banana. The second box was nonfunctional in design as it could not be stood upon. Thus, it could be moved but was not appropriate for solving the problem of reaching the banana. The pushing box training of the Pigeon 1 was with three boxes (the red box and the two new blue boxes) presented randomly, but the training of standing and pecking was done with the red box, the functional one. Pigeon 2 was experimentally naïve, and its training was conducted using the red box for the standing and pecking behavior and the two blue boxes for the pushing. Both pigeons learned to move the two boxes to a black target dot during training. There was no difference in their

ability to move either box to the target dot, and pigeons were tested in the displacement problem for the first time with both boxes. Then, Pigeon 1 participated in two baseline training sessions, and Pigeon 2 received seven baseline training sessions, and both were tested for a second time in the two-box displacement test.

In the first two-box displacement test, Pigeon 1 exhibited no differential behavior toward the functional box, and it did not solve the test. Pigeon 2 exhibited differential behavior to the boxes pushing the functional box and solved the problem, but it displaced the box around the arena for more than 180 s, so the authors did not consider an insight resolution as the pushing was undirected toward the banana goal. In the second two-box displacement test, Pigeon 1 had a similar performance as in the first test and did not solve the problem. Pigeon 2 showed no differential behavior between the two boxes this time, although after 262 s, it pecked the banana and solved the problem. Finally, only with Pigeon 2, the authors did a single-box displacement test with the functional box present without the nonfunctional box, and the pigeon solved the test in 24 s, enough to consider it as an insight resolution.

The conclusion of Cook and Fowler (2014) is that pigeons solved the single-box displacement test due to the temporal and spatial relations of the physical elements in the task and their prior trained behaviors, although without a means-end understanding of the elements of the problem. Nevertheless, we should consider these results with caution because the sample size is small ( $n = 2$ ) and one of the pigeons actually showed a preference for the functional box in the first test, even though it solved the second two-box displacement test. To show two boxes at the same time could interfere with the solution of the test by adding difficulty and confusion to the problem situation, maybe as a result of a competition between stimuli reinforced previously and overshadowing of the emergence of standing behavior. Also, it is not clear if pigeons can distinguish visually between boxes and if they can predict their functionality because, at the moment of the test, they have not yet climbed on them. So, more research is necessary to prove the lack of pigeons'

means-end understanding, perhaps exposing pigeons to stimuli with different functions and testing if they choose the most useful in a simpler task would provide such evidence.

## Conclusions

The insight studies on pigeons have demonstrated the relevance of the subject's learning history for the insight and how the topography of the response during the test is dependent on it. As Luciano (1991) maintained, the responses necessary to perform the solution to the problem should be learned in some way before the problem exposition in order for each stimulus under the test conditions to become a functional stimulus for response chaining to occur. However, there are some factors that can interfere in the emergence of insight, as the arrangement of the problem situation, number of stimuli present, type and quantity of behaviors required to solve it, and type and structure of training.

Epstein (1985, 1987) demonstrated that the number of behavior repertoires trained and the number of stimuli present in the test are important variables. Just like in the arrangement of Cook and Fowler (2014), the more stimuli are controlling pigeons' behavior, the more complex will be the problem situation for them. It generates a greater competition between the behaviors controlled, and, therefore, the solution would probably be less fluid. The same happens with the number of behaviors trained, considering that only the most probable behavior is performed and the pigeon can only perform one at a time, but other behaviors can also be highly probable to occur at the same time. Luciano (1991) showed that the responses that have been previously acquired in relation to the stimuli also present in the test will be more likely to appear in as they were previously carried out.

On the other hand, the question still remains unsolved about the relation between higher cognitive capacities such as reasoning, associative learning (Andrews 2015), and insight. In animals like pigeons, this question is still more complex because they have generally been considered

cognitively simpler than mammals and even other birds such as corvids and parrots (Emery and Clayton 2005). Some authors consider that the specific training invalidates the emergence of insight because spontaneous problem-solving is caused only by specific cognitive processes that came from a specific phylogeny without previous learning (Taylor et al. 2010). Other authors support the idea that means-end understanding could be only a human characteristic (Povinelli 2000).

We should focus here on how the specific training is different from other previous experiences as free exploration or indirect learning in order to define means-end reasoning as opposed to it because previous learning of some behavioral repertoires that are required in a specific problem situation can be a determinant to solve. The specific training of prerequisite behaviors to solve a problem does not necessarily involve learning a rigid sequence of behaviors, but it can lead to a recombination of them in a flexible way to perform the sequence that best suit the problem situation (Voronin and Firsov 1967, cited in Reznikova 2007). To a certain degree, this is similar to some investigations on problem-solving where subjects are exposed to different types of problems throughout their research; as was the case in the Köhler studies, although they did not learn directly how to solve a specific problem, they have a greater repertoire of behaviors, so more interconnections can occur in a future problem situation (Neves-Filho et al. 2016). So the point is that the relevance of the phenomenon of insight would be not only to investigate the emergence of it but also to focus on the process that leads to its emergence.

## Synonyms

Aha moment; Deep understanding; Eureka effect; Reasoning

## Definition

Insight is a spontaneous, continuous, and direct way of solving a problem, also called Eureka effect or Aha moment. In rats, it is defined as spontaneous interconnection of behaviors to reach a goal and has also been related to the concept of causal reasoning.

## Introduction

Köhler was one of the first authors who proposed the spontaneous way of solving problems as opposite to a gradual or trial-and-error solution. He tested in apes the use of roundabout methods to achieve a goal in different tasks, also called “Umweg” or “detour” problems, and he came up with the German word “Einsicht” to define the process of spontaneously solving them. The

word was translated in English as insight in *The Mentality of Apes* (Köhler 1925).

At the beginning of the twentieth century, investigations were carried out on the spontaneous resolution of problems in rats, called insight. However, the definition of insight has been controversial since the word *Einsicht* was translated; the most cited and standard definition until now (Foerder et al. 2011) is Thorpe's (1956) "sudden production of new adaptive responses not arrived at by trial [error] behavior. . . or the solution of a problem by the sudden adaptive reorganization of experience" (p. 100).

Helson (1927) was the first publication in rats with the term "insight in the white rat." The principal objective of his study was to measure rats' visual perception learning and to determine if the rat's response was conditioned to the element connected with the goal or if there was a structural and functional learning of the specific problem situation, so the elements in the situation could change while the response was maintained. Helson related this experiment in rats with Köhler's experiments of insight in apes defining insight as an "ability to respond to a part in the light of the whole, a modification of activities to meet the exigencies of a situation in a manner we may call sensible, or the transposition of the general properties from one situation to another" (p. 380).

In Helson (1927), four rats were exposed to different intensity stimuli: gray color scheme and degrees of illumination. Rats were placed in a room with two compartments both with food, each light intensity was randomly assigned. In the first five series, Rat 1 and Rat 2 received food in the brighter gray color or light (60-watt vs. 15-watt) compartment, and Rat 3 and Rat 4 received food in the darker one (60-watt vs. 15-watt light). If the rat entered the wrong side, the plate with food was removed out of its reach. In the last four series, the values of intensity of the stimuli changed; for example, for Rat 1 and Rat 2, the brighter light was of 150-watt, and for Rat 3 and Rat 4, the darker light was of 1-candle-power (cp) light.

Helson (1927) concluded that there was insight in the rats' behavior because they followed structure-function principles and not connections

between identical elements. "Rats responded to and retained the structure, neglecting the absolute element as such; for example, although Rat 1 and Rat 2 had been choosing the 60-watt light in the first five series of experiments, when presented with the 15-watt light, they chose the brighter and neglected the 60-watt light as they had previously been neglecting the 2-cp light" (pp. 383). Rats learned to follow the brighter light in opposition to the specific stimuli conditioned, the 60-watt light. This learning rule imply that rats adapted better to dynamic but consistent environments, through a cognitive-like reasoning approach.

## Testing Rats' Insight in Mazes

Tolman and Honzik (1930) published the second article of insight in rats in which they conducted three experiments with different mazes. They defined insight as "a material, inner relation of two things to each other" that can be seen in the response as sudden changes in response. The authors hypothesize that some learning occurs in the absence of observable changes in performance, and it does not manifest until the reward is introduced, when the response appears in an insightful way.

The first experiment consisted of a replica of Hsiao's (1929) experiment, but this time with more subjects. They used the same labyrinth to test rats' insight. Rats had to infer that, if a common section was closed, none of the paths led to food access, so the only alternative was to take a third path to get the food. They trained rats to run through the paths and develop a strong preference for Path 1, a less strong preference for Path 2, and a weak or no preference for Path 3. They found that 4 of the 10 rats tested avoided Path 2 after returning out of Path 1 in the first group and 1 of 11 rats in the second group. Therefore, they concluded that the results were not sufficient to prove insight in rats, and they conducted a second experiment in which the maze was modified to require a larger movement between Paths 2 and 3. It was found that 5 of 11 rats avoided Path 2 on the first run, but they argue that these results were not clear to conclude that subjects chose pathways based on

the most efficient way to reach the goal and not on the strength of the pathway's habit.

In the third experiment, Tolman and Honzik (1930) built an elevated maze with similar characteristics: three different paths to reach the final box. They scored the number of dead-end arms rats entered, considered as errors, during each trip from start to goal box. They created three groups: reinforcement, not reinforcement, and delayed reinforcement. The reinforcement group was always rewarded with food when rats reached the end of the maze, and the number of errors decreased dramatically as a function of the number of trips they made. Rats in the not reinforcement group were just taken out of the maze when they reached the end of it, committing more mistakes, and rats in the delayed reinforcement group were taken out of the maze for the first 10 days, but rewarded at the end of it on the eleventh and subsequent trials. In this group, the number of errors made dramatically decreased on the twelfth and subsequent trials, even more than the reinforced group. The authors explained that rats in the delayed reinforcement group developed a "cognitive map" of the maze during exploration and that such mental representation guided the behavior in the rewarded sessions – evidence that learning can occur without performance. The insight run was given on the fourteenth day, and they found that, in the first run, 14 of 15 rats in Group A and 7 of 10 in Group B avoided Path 2, taking Path 3 immediately, in spite of the strong preference and habit for Path 2 acquired during the training period. They concluded that rats can show insight behavior when they can see the situation as a whole in an elevated maze.

Replications of Tolman and Honzik's third study with rats (Caldwell and Jones 1954; Gilhousen 1931) obtained similar results. Notwithstanding, the authors questioned the term insight as an explanation of the data, due to the lack of operationalization of the concept, so the interpretation of the solutions is ambiguous. For example, Caldwell and Jones (1954) explained that if insight is defined as one-trial learning which is subsequently maintained, then this definition was not applicable in their replication, because the subjects did change their performance in subsequent trials. They suggested a redefinition

of the concept that encompasses this non-maintained performance; otherwise, it could be explained in terms of associative learning.

Gilhousen (1931) highlighted factors to account for the emergence of insight. He tested insight in rats with an elevated open maze, a solution to the problem required suddenly to oppose previous habit and preference. Rats were trained to go through a jumping path to avoid going through a running block path to a food box. The hypothesis was that the more jumps rats must do, the harder that path will be, so they will choose the running path instead of the jumping-habitual path. In the test, Gilhousen moved the paths closer, so the rat had the opportunity to avoid most of the jumps, running to where it was blocked through the running path and then taking a single jump to get to the food through the jumping path. However, all rats continued choosing the jumping path in the test.

Gilhousen suggested that factors such as the type of behaviors requested to solve the problem, the dimensions of the maze, or the amount of previous training affect the emergence of insight. Running and jumping constitute separate abilities, which hinders the sudden change from one behavior to another. An unbiased test would require more similar behaviors. It would be relevant to study the effects of varying the dimensions of the maze, as it would require different abilities to jump. It could be expected that the longer the rats were required to jump, the more effort would be involved, so the rat would prefer the other path. In addition, the amount of previous training given can be important because the more training is given, the stronger the habit will be, and therefore, the appearance of a sudden change of behavior will be reduced.

### **Fortuitous Observations of Insight in Rats**

Hamilton and Ballachey (1934), in an experiment on social behavior in rats, observed one of the rats solving their task in a different and insightful way. Rats had to climb over a barrier to access a tin of food in an open area. They usually did not eat it there but took a piece of food from the tin and

returned across the barrier to eat it in a smaller enclosed space. One of them seized the tin and dragged it to the barrier and jumped to the top of the barrier, so the food tin was temporarily out of her visual field, and then “slowly leaned forward and down, grasped the tin again with her teeth, pulled the tin to the top of the barrier and dropped it on the inside” (p. 260). The authors considered this behavior an example of insight because the rat did it in a spontaneous and goal-directed way.

Another example is Ewer (1971), who conducted different tests in free-living rats to investigate performance when food was placed out of their reach. A task consisted of vertically pulling a string with a nut attached, and the rats took no more than two trials to find out how to pull the string up and reach the nut. Ewer concluded that, although the rats did not solve the tests on the first attempt, they did not show learning by trial and error, but by trial and success, because “once a success was achieved, even if this was more or less by chance, they were extremely quick to learn what to do” (p. 164).

The definition of insight proposed by Ewer (1971) created confusion in the area and is one of the problems that still persist. The behavior described by Ewer (1971) may not be strictly insight because the solution, the first response, appeared after several attempts; however, maintenance was sudden and quickly obtained, so this may be an example of faster learning but not truly insight. Nonetheless, the description may fit what most people think of as insight. The problem becomes then of interpretation; how fast should the response be to be considered as insight? Could the solution in the second attempt be considered as insight, or is the experience with the first trial sufficient to consider the solution as a result of trial-error learning? These questions are still in need of resolution.

## Hebb's Theory of Insight

Hebb proposed one of the earliest theoretical analyses of insight in *The Organization of Behavior* (1949). Hebb manipulated rats' experience before exposing them to novel problems. He found that

faster learning abilities and insightful solutions were more common in laboratory rats that freely explored his home and were manipulated as pets than in rats housed in standard laboratory conditions. Also, he explained that there is a permanent effect of early experience on problem-solving, so animals exposed to specific environments can have the requisite experiences, which can be interconnected to solve new problems presented in adulthood.

In Hebb's theory, the insight is an organized set of responses to a new situation that arises from the reorganization and integration of experiences that have been learned given specific consequences, but such new organization has not been learned. Hebb emphasized the necessity of experience in the emergence of insight, just as Maier (1935) pointed out in rats.

Hebb (1949) considered that insight continually affects learning, because it complements it, and, thus, the distinction between learning and insight must be a matter of degree. He concluded that insight is not a separate phenomenon from learning because it is part of the same processes. He claimed that Köhler's chimpanzees could have been using both associative learning and causal reasoning to solve problems. There is no need to limit insight to situations when there is a fast solution of the problem, but also delayed solutions can be conformed in a similar way, for example, after a confusion period that could take a time or even several trials. This approach is consistent with Ewer's (1971) definition of insight.

## Insight: Is It a Synonym of Reasoning in Rats?

Extensive research with *detour* or *Umweg* problems was conducted by Maier (1935) with rats. The problems were situations where the subjects have to overcome an obstacle, so they had to use a roundabout method to achieve a goal. He postulated that, when solving a problem, two distinct abilities interact: (1) to integrate contiguous experiences as described by the laws of association, which he identified as learning, and (2) to bring together spontaneously elements of past

experience without having them previously associated by contiguity, which he designated as reasoning. Therefore, for Maier, the phenomenon described by Köhler as insight was termed “reasoning.” He was the first to claim that spontaneous integration of different experiences was insight learning.

One of the mazes that Maier built to assess reasoning in rats (1929) consisted of placing rats on a table with a ladder that gave access to the ground. The table was divided by a grating that prevented rats from entering the other part of the table. Experience I involved the rats walking freely through the place. In Experience II, a second table was positioned with an elevated pathway connecting the inaccessible location of the first table. The second table had three ring stand ladders that connected it to the ground. At this stage, the animals climbed from the ground to the new table and crossed the bridge from the new table to the inaccessible area of the first table. The test consisted of placing the animals at the first table and presenting food in the inaccessible area of the first table. Animals should recombine Experiences I and II to solve the problem. Maier analyzed the number of correct responses, time scores, and the directness of the run and concluded that experienced rats were able to recombine them, but rats without Experience I or II failed to solve this task.

In contrast, Wolfe and Spragg (1934) did not replicate Maier’s results (1929) using three adaptations of Maier’s apparatus with both elevated and enclosed pathways. They found that rats’ performance was not superior to chance, so rats were apparently unable to combine two segments of behavior successfully. In a fourth variation, the behavior of Maier’s rats was replicated, but Wolfe and Spragg criticized the amount of training that rats needed to get it. They concluded that success in the task cannot be called reasoning because the training procedure would have introduced learning (i.e., association by contiguity) and solutions were achieved in “a manner entirely consistent with ordinary learning principles” (p. 469). Maier (1935) argued that the amount of training does not mean that they learn to recombine more easily because the route to food cannot be learned,

since it is different each day. They increased their exploration but not their ability to find which path leads to food, because the training does not determine which path leads to food on a test.

Other possible methodological variables that Maier emphasized as important when recombining experiences are the training procedure and the differences in the apparatus. Wolfe and Spragg did not carry out a general exploration period on the days of the tests and changed the position of the food box and starting point in the maze. If the pathways to be selected were near the starting point, rats easily chose a pathway without a possible appearance of a confusion period, committing mistakes. Instead, when the starting point was next to the food, which was behind a wire obstruction, rats attempted to reach it first without success, and during this confusion period, they can “reason” which path to take to reach the food.

Shepard (1933) also used the term reason in rats and defined it as adaptive reactions that are “a combination, in advance of the reaction, of factors from separate experiences, and where such separate experiences involve essential contradictory or differing elements that must be functionally recognized” (p. 149). He exposed rats to enclosed mazes with food boxes with different start points, alleys, sections, and shortcuts. One maze consisted of long *cul-de-sacs* and a subsequent correct path to food. After letting the rats thoroughly explore it, a shortcut was opened in one of the dead ends. In the first trial, it passed the blind as usual but paused when it came to the new opening, explored the area, and went through it to the food box. Then, the rats were removed and placed at the start point again. Most of the rats turned at the appropriate junction and took this former blind alley to go directly to the food. Shepard suggests that rats reasoned because they spontaneously took the shortest path to the food.

More recently, comparative psychologists have been interested in causal reasoning and other cognitive processes mediating problem-solving behavior. Some studies with rats found evidence of causal reasoning using instrumental and Pavlovian procedures (Blaisdell et al. 2006; Polack et al. 2013). However, in these cases, causal reasoning is not defined as a spontaneous

combination of experiences but as rats' inferences about their actions and other events in the future, a trait that is implicit in the insight phenomena (Shettleworth 2012). Some other researchers prefer to just describe the behavior as "spontaneous or innovative problem-solving," because the insight concept may have hypothetical cognitive mechanisms underlying further implications, as planning actions (Taylor et al. 2012).

### Insight as Spontaneous Interconnection of Behaviors in Rats

A classic test to study insight in animals was developed by Epstein et al. (1984): the box-displacement task. This test is an adaptation of Kohler's experiment with chimpanzees in which a banana was suspended in the ceiling and the subject had to stack boxes to reach it. In Epstein et al.'s (1984) experiment with pigeons, the banana was replaced by a plastic banana, and every time it was pecked by the pigeon, food was given. In the test, the pigeon had to move a box under the plastic banana to reach it. Pigeons were able to solve the task in a direct, smooth, and continuous way, after specific training of three prerequisite behaviors: to push a box, to climb onto a box, and to peck a banana. Epstein et al. considered these solutions evidence of insight in pigeons and proposed the "generativity theory" (Epstein 1990) to better characterize the phenomena as "spontaneous interconnection of separate repertoires of behavior" (p. 117). For more information, see *Insight in Pigeons* (► "Insight in Pigeons" by Longán and Buriticá, this volume).

Leonardi et al. (2011), based on Epstein's theory, reported four experiments using the box-displacement task to obtain evidence of insight in rats. In rats, the displacement-box task is like Epstein et al.'s (1984), but instead of pecking the banana plastic, rats had to pull a chain with a ring attached to a bar that activated a water dispenser. Rats were trained to do three prerequisite behaviors: to push a cube directionally toward a point of light that was changing position, to climb onto the cube, and to pull the chain (Leonardi et al. 2011). Nevertheless, rats did not show insight in this task,

except one, which solved the task in a sudden, direct, and continuous way, but required more than one test and additional training of prerequisite behaviors.

Leonardi et al. (2011) suggested that rats' negative results could be due to the importance of visual cues to solve this task. The albino rat appears to have consistently impaired visual acuity, and this high-effort visual task is demanding for rats. So, in comparison with chimpanzees and pigeons, this task could be more difficult for this specie and strain. Likewise, the authors noted other procedural variables that could be affecting the ability to spontaneously solve problems: if the learning criteria of the prerequisite behaviors are strict, as well as if rats are trained in the same order in which the resolutions are expected, insight resolutions are more probable to appear during test.

Based on Maier's study, Neves-Filho et al. (2015) showed insight in rats in a new problem situation called "the dig and climb test." The task was to place a rat in a cage where food was visible but unreachable. The cage was divided into two parts by a transparent acrylic barrier. On the left side, the ground was full of sawdust. On the right side, there were ladders that gave access to the platform with food. The transparent barrier had a hole, covered by sawdust, connecting both sides of the cage. So, the rats in the right side had to dig in the sawdust until they found the hole, cross it to get to the other side of the cage, and to climb the ladders to access the food. The behaviors that expected to be spontaneously recombined were (1) to dig in the sawdust and (2) to climb a ladder.

All rats had a pretest session to establish if they were able to solve the task just by exploration, without any training of the prerequisite behaviors, but none of the six rats tested solved the problem in the pretest. Then, Neves-Filho et al. created three groups of two rats each. The full group learned the two prerequisite repertoires, while the other two groups lacked training of one of the two repertoires; one was called digging group, and the other one climbing group. Once all rats reached a learning criterion of the behaviors, they exposed them to the problem. In the test, only the full group solved the task in an "insightful" way. They described the resolution as "the

two subjects crossed the hole as soon as they found it, and immediately climbed the two ladders" (p. 8), one in 83 s and the another in 135 s. The performance was like Epstein et al. (1984) behavior in pigeons, that is, in a continuous, fluid, and direct way, although Neves-Filho et al. recognized that "insight is not a clear operational term to describe problem-solving behaviors" (p. 11). For example, there are no specific time criteria to define a solution as insight or trial and error.

Neves-Filho et al. (2015) also did a post-training of the lacking behavior to the climbing and digging groups and a post-test in the same task. In this case, one out of the four subjects solved the task but with pauses between crossing to the other side of the chamber and climbing the ladder. To explain this difference, Neves-Filho et al. suggested that the type of training affected the sudden solution of the problem. In the case of the full group, the training was concurrent; that is, one behavior was trained just after the other; while in the case of the climbing and digging groups, the behaviors were trained at different times, independently or sequentially. As just concurrent training showed spontaneous solving of the task, the authors point out that it facilitates insight rather than an independent training of the behaviors.

Further, Neves-Filho et al. (2016) examined the differences in rats' insight in the dig-climb task using different types of training and orders in the sequence trained. Surprisingly, subjects of all experimental conditions solved the final task ( $n = 5$ ), and two did it by insight. One subject of the group with both behaviors trained at the same time (concurrent), and another trained first with one and then the other (sequential). Therefore, they conclude that order of training did not increase the emergence of insight. However, they did find that the rats trained concurrently solved the problem in a shorter time than the sequentially trained ones – data that provides some evidence that the type of training can affect the spontaneity in resolution. They argue that the use of a less strict behavior learning criteria than Neves-Filho et al. (2015) could have negatively affected the emergency of insight, so more research is needed to confirm these hypotheses.

Using "the dig and climb test," Longán and Buriticá ("Effects of Environmental Enrichment in the Insight in Rats", in preparation) studied the effects of environmental enrichment in the insight and problem-solving in rats in different types of training and order of behaviors. The experimental group ( $n = 8$ ) were reared under enriched housing conditions in trios; in such conditions, the animals could develop an ample repertoire of behaviors (to move in different surfaces, social interactions, etc.) through interaction with conspecifics and different objects like an activity wheel and various materials such as wood and fabrics. A control group ( $n = 9$ ) lived in trios in common housing: acrylic box with sawdust.

Longán and Buriticá established that an insight resolution must be as Epstein et al. described: continuous, fluid, and direct. The link between the two prerequisite behaviors should take a short time to be considered as insight, and other behaviors should not be performed between them. In the first exposure to the problem without any training, called pretest, one rat of the social group and three rats of the enriched group solved "the dig and climb test," one of the enriched group by insight (37 s between the two prerequisite behaviors). Then, a training of one prerequisite behavior was done, and after rats reached the same behavior learning criteria as Neves-Filho et al. rats were exposed to Test 1. One rat of the enriched group solved the task by insight (19 s) in Test 1, after the climbing behavior training. Then, rats learned both prerequisite behaviors in a sequential training, and a second test was done (Test 2). One more rat of the enriched group solved it by insight (22 s), and none of the social group subjects solved the task in Test 2. As in Neves-Filho et al. (2016), no significant differences were found in the order or type of behavior training. Instead, the enriched group was faster in reaching the climbing learning criteria than the social group. These results provide evidence that environmental enrichment facilitates insight, problem-solving, and response acquisition, supporting the hypothesis proposed by Hebb.

Finally, Dicezare (2017) designed a new insight task in rats based on Köhler (1925) in chimpanzees. It consisted of pushing a cube

toward a platform and climbing on it and then onto the platform to get food. A concurrent training was carried out of two prerequisite behaviors: to push the cube toward a lit partition and to climb on the cube and on a platform. Other ways to climb on the platform were extinguished. Rats ( $n = 2$ ) solved the problem in a spontaneous, direct, and continuous way. They performed the second behavior (to climb) right after finishing the first behavior (to push), with 1 second of difference. It was concluded that the procedure adopted made possible the emergence of insight in rats in a methodologically similar way to that used by Epstein et al. (1984) in pigeons.

## Conclusions

The recent insight research with rats suggest that its study may not require such elaborate problems or specific species. Spontaneous problem-solving in rats has been demonstrated in several studies for a century, and it is still studied nowadays. Despite great efforts, the term “insight” remains confusing in relation to the processes that underlie it. More elaboration and specificity of the phenomenon through behavioral and time criterion are needed to provide a solid measure to evidence it and identify its mechanisms.

The literature established the importance of experience like specific training or environmental enrichment to the emergence of insight in rats. Training of prerequisite abilities may be enough for the interconnection of behaviors to occur, but there are also variables that can hinder the appearance of insight, for example, the specific difficulty of the problem task to the specie or the amount of experience related to the task (i.e., low learning criteria), while environmental enrichment can favor the acquisition of new behaviors and the emergence of insight in rats.

The theoretically contentious question is whether insightful behavior is the product of a special mechanism or process, as opposed to processes used in routine problem-solving like trial and error. The relation between higher cognitive processes such as reasoning, insight, and associative learning still remains unsolved, due to the lack

of observational data to evidence it. Rather, attempts at showing such cognitive processes must first demonstrate that insight study cannot be accounted for in terms of associative learning. Some pioneering studies are already solving this question demonstrating neural correlation with the phenomenon in rats to explain sudden responses in problem-solving (Durstewitz et al. 2010).

## Instinct

Robert J. Richards

Departments of History, Philosophy, and Psychology, The University of Chicago, Chicago, IL, USA

In the *Origin of Species*, Darwin (1809–1882) endorsed what he took to be the common notion of instinct: "An action, which we ourselves should require experience to enable us to perform, when performed by an animal, more especially by a very young one, without any experience, and when performed by many individuals in the same way, without their knowing for what purpose it is performed, is usually said to be instinctive" (Darwin 1859, p. 207). He then proposed that instinctive behavior in animals could be explained using the resources of his theory, such behavior essentially being no different than other adaptations. Darwin's characterization of instinct would have been recognized by many naturalists writing long before the nineteenth century and long thereafter.

## Theories of Instinct Prior to the Nineteenth Century

In the second century of the common era, Claudius Galen (130–210) performed what became known much later as the deprivation experiment. He took a young goat from its mother by cesarean section, thus preventing any opportunity for learning. He and his colleagues then placed before the young kid several bowls of food stuff – wine, oil, milk, honey, etc. After sniffing at each of the bowls, it started lapping

up the milk. He and his assistants gave a yell, seeing realized what Hippocrates had said: “the natures of animals are untutored” (Galen 1824). Galen’s procedure, while not without problems, yet meets the general requirements of the “deprivation experiment,” which Konrad Lorenz (1903–1989), in the twentieth century, specified as the empirical foundation for his own conception of instinct: deprive an animal of any opportunity to learn and if it yet exhibits a species-specific pattern of behavior, then that behavior is innate and can be called “instinctive” (Lorenz 1965, pp. 83–100).

In the Medieval Period, Avicenna (980–1037) developed a theory of instinct based on Aristotle’s notion of incidental perceptibles – e.g., the white milk being incidentally perceived as sweet. The distinctive and skillful behaviors of animals convinced him that their souls had an estimative faculty, an internal sense that detected meanings (*intentiones*) not available in the immediate data of the external senses. This awareness resulted from a divine inspiration that the Latin translator variously rendered as *cautela naturalis* and *instinctus insitus* (Avicenna 1968–1972, vol. 2, pp. 37 and 73). Thomas Aquinas (1225–1274), in his own commentary on Aristotle, described this faculty of the animal soul as a “natural estimative power (*aestimativa naturalis*) given to animals through which they are directed, in their actions and passions, to seek or avoid things appropriate to their nature” (Aquinas, lec. 13).

In the seventeenth century, René Descartes (1596–1650) rejected the notion of the medieval Aristotelians that animals had a particular kind of soul with capacities of sensory cognition. Descartes regarded animal behavior as explicable according to mechanistic laws. Yet both Descartes and the Aristotelians agreed that complex animal behavior (e.g., birds’ building their nests or bees’ their cells) had to be explained by instincts, which they understood as fixed patterns of behavior determined by the Creator for the welfare of his creatures.

A reaction set in against the very idea of animal instinct during the eighteenth century. The Abbé de Condillac (1715–1780) argued for a continuity between animal and human intelligence, holding

that intelligence arose simply from the association of ideas, which were only less vivid images derived from sensation. So that what was taken as innately determined behavior could better be understood as originally intelligent behavior that had become habitual (Condillac 1798, vol. 3, pp. 435–439). Jean-Antoine Guer (1713–1764) also adopted this sensationalist epistemology. He asserted that the ascription of instinct to animals confounded any attempt at reasonable explanation, for “nothing is easier to say about whatever animals do than they do it from instinct” (Guer 1749, vol. 2, pp. 191–192). The sensationalist position ultimately derived from the rejection by Locke and other empiricists of innate ideas, whether in humans or animals (Richards 1979).

Those researchers that studied animal behavior with care had strong evidence on their side. Hermann Samuel Reimarus (1694–1768), for instance, pressed the kind of experimental observations undertaken by Galen, namely, that animals exhibited arrays of fully formed, complex behaviors before they had any opportunity to learn them: chicks shortly after emerging from the egg could peck at grain with coordinated movement and caterpillars that had never seen a cocoon skillfully wove one in the same design as their ancestors. Automatic behavior that characterized most members of a species seemed hardly different from anatomical traits and was so regarded by early evolutionists (Richards 1987).

## Early Evolutionary Conceptions of Animal Instinct

Erasmus Darwin (1731–1802), grandfather of Charles, trained as a physician at Edinburgh medical school, whose faculty had, during Darwin’s student years, received their own education at Leyden, where the mechanistic ideas of Herman Boerhaave (1668–1738) largely prevailed. In his medical treatise *Zoonomia* (1794), Darwin joined a mechanistic materialism with a sensationalist physiology. He proposed that a subtle fluid – the so-called *spirit of animation* – coursed through the brain and nerves causing contractions of muscle fibers. This fluid reacted to both internal and

external stimuli and operated according to principles of association, so that “all animal motions which have occurred at the same time, or in immediate succession, become so connected, that when one of the them is reproduced, the other has a tendency to accompany or succeed it” (Darwin 1796, vol. 1, p. 320). The nervous fluid formed ideas within the brains both of animals and humans, ideas that were only faint copies of sensations (pp. 105–107). Darwin’s sensationalist psychology thus allowed him to assume continuity between animal intelligence and human intelligence. It also allowed him to assume that those patterns of behavior usually assumed as instinctive actually arose from intelligence and habit. For instance, he regarded nest-building in birds as the result of observation and “their knowledge of those things, that are most agreeable to their touch in respect to warmth, cleanliness, and stability” (pp. 171–173). It took a bit more ingenuity, however, to explain those patterns of behavior that some animals expressed just after birth, without obvious opportunity to learn, for example, the coordinated pecking and swallowing by newly hatched chicks. But Darwin was not without imaginative resources. He supposed that the chick, while still ensconced in the egg, would be continually gaping and gulping embryonic fluid, thus induced to practice and learn the very behaviors it would exhibit after hatching (pp. 138–139). (In the 1920s, the radical behaviorist Z. Y. Kuo made similar objections to the isolation experiment. Using examples comparable to those of Darwin, Kuo argued that conditioned learning could occur even while the chick was still in the egg. See Kuo 1929).

Despite his sensationalist biological assumptions, Darwin advanced a powerful evolutionary conception. His theory allowed for traits acquired by ancestors to be passed to offspring; like Lamarck, he was convinced of the inheritance of acquired characteristics. Anatomical traits acquired by parents through exercise – e.g., the blacksmith’s strong arms – could be passed to offspring, with the tendency to vigorous arm movement, for instance, already begun in the womb. Embryology allowed Darwin to project the processes of learning back to the very beginning:

All warm-blooded animals have arisen from one living filament, which THE GREAT FIRST CAUSE endued with animality, with the power of acquiring new parts, attended with new propensities, directed by irritations, sensations, volitions, and associations; and thus possessing the faculty of continuing to improve by its own inherent activity, and of delivering down those improvements by generation to its posterity, world without end! (Darwin 1796, vol. 1, p. 509)

While Darwin’s evolutionary account did not mesh well with his sensationalist psychology when trying to explain stereotyped patterns of behavior, another early evolutionist, also of sensationalist inclinations, was much more successful in giving an evolutionary account of instinctive behavior.

Jean-Baptiste de Lamarck’s (1744–1829) three-volume *Flore française* (1778) helped advance him to membership in the French Academy. His systematic survey of French plants brought him to the attention of Georges Leclerc, Comte de Buffon (1707–1788) at the Jardin des Plantes, where Lamarck was later appointed to the chair of botany in 1788. After the Revolution he was made professor of zoology in the *Muséum national d’Histoire naturelle*, where he was put in charge of insects and invertebrates. His extensive study and classification of mollusks brought him international celebrity among his peers. In 1800, this conventional, if highly technically competent, zoologist gave a talk at the *Muséum* that set him on a radical path. In his “Discours de ouverture,” Lamarck proposed that animals adjusted their behaviors to changing environmental circumstances and that the resultant modifications of organs would be heritable, producing new alterations in species (Lamarck 1801). Shortly thereafter he added another principle to account for the slow change in species over time. In his *Recherches sur l’organisation des corps vivans* (1802), he maintained that the imponderable fluids of caloric and electricity, acting on mucilaginous materials in the earth, could generate small, living monads and that the continued activity of these fluids would produce gradually more complex organisms. These two principles became the anchors of his *Philosophie zoologique* (1809), where his evolutionary theory came to completion (Lamarck 1809). The imponderable fluids would

continuously bubble up new organisms and push them to greater complexity, while habit becoming instinct would alter organs keying them into environmental niches.

In his *Discours d'ouverture* of 1814, Lamarck defined instinct as “that singular power which operates without premeditation and from the consequences of felt emotion” (Lamarck 1972, pp. 179–185). He distinguished it from both intelligent acts, which do not always attain their desired end, and mere habits that were not driven by a felt need. Moreover, specific instincts characterized a whole species of animal; they were not idiosyncratic expressions.

Lamarck's evolutionism found some allies in his native country – e.g., Etienne Geoffroy Saint-Hilaire (1772–1844) – and several early adherents in Germany, such as Friedrich Tiedemann (1781–1861) and Gottfried Reinhold Treviranus (1776–1837). In Britain, Charles Darwin's early tutor Robert Grant (1793–1874) thought his own study of sponges supported Lamarck's transmutation hypothesis. But Lamarck's theory met crushing opposition from the doyen of French Naturalists, Baron Georges Cuvier (1769–1832). In the introductory volume of his *Recherches sur les ossements fossiles* (1812), Cuvier mounted three objections that would be reiterated against Darwin's theory: (1) no transitional species are found in fossil deposits; (2) experience shows that species only vary in nonessential traits; and (3) mummified animals from ancient Egypt are recognizably the same as those found in modern Egypt (Cuvier 1834, vol. 1, pp. 198–218). In his *éloge* for Lamarck, his recently deceased colleague, after citing a few respectable achievements, Cuvier came to the infamous theory and reduced it to rubble. In his caricature: “It is the power of the desire to swim that produces the membranes between the toes of aquatic birds; it is by reason of going in the water but wishing not to get wet that river birds have their legs lengthened; it is the power of desiring to fly that has changed their arms into wings and has developed their hair and scales into feathers” (Cuvier 1835, p. xix). Lamarck's theory later fell on ears more receptive, those of the young Charles Darwin.

## Darwin's Evolutionary Construction of Animal Instinct

Though fully aware of his grandfather's views and Lamarck's theory, Charles Darwin remained orthodox in his biology while on the Beagle Voyage (1831–1836). It was only when he returned to England and started cataloguing his materials that he began to speculate on species change. He had sent back to the British Museum large samplings of organisms, among which were three varieties of mocking bird, taken from different islands of the Galapagos. Since the islands were volcanic and relatively young, Darwin assumed the birds had gotten blown over from the mainland and that their morphological alterations were merely varietal, induced by the different environments of the islands. When John Gould (1804–1881), the chief ornithologist at the Museum, contended that the birds represented three different species, he tripped a mind at the ready (Sulloway 1982). Darwin began immediately speculating on species change in spring 1837, and in various early notebooks (March 1837–June 1838), he considered what might be the causal factors that produced species change. He immediately considered Lamarck's imponderable fluids but quickly concluded: “all structures either direct effect of habit, or hereditary effect of habit” (Darwin 1987, p. 175). He argued to himself that new habits, if practiced by a population over long periods of time, would turn into instincts and that these latter would eventually modify anatomical structures and so would alter species. From Darwin's perspective, the intermediary of instinct would preclude any conscious, intentional activity on the part of animals, and so his nascent theory would not be subjected to the common charge brought against his predecessor that animals supposedly willed themselves new parts. Darwin, undoubtedly, was engaged in a bit of self-defensive scholarship. His own device of species change in this early period hardly differed from that of Lamarck; his modification of the essentially Lamarckian device could shield only a naïve researcher. Darwin's confidence grew after he formulated his chief principle of natural selection. Yet, Darwin never abandoned the idea

that the environment could directly induce heritable changes and that habit could ultimately give rise to instincts and alterations of species. These assumptions are feathered throughout the *Origin of Species*, but they became secondary causes to his new discovery of natural selection in fall of 1838 (Richards 1987).

In early fall of that year, Darwin, as he recalled in his *Autobiography*, picked up “for amusement” Thomas Malthus’s *An Essay on the Principle of Population* (Darwin 1969, pp. 119–120). With the reading of Malthus’s *Essay*, he had the beginnings of the idea that would blossom into natural selection. Malthus provided him the idea of population pressure under scarce resources, which might produce a struggle for existence. All of this “wedging,” as he called it, had the “final cause” of filtering out all but the most fit organisms and thus adapting them (actually, leaving them preadapted) to their circumstance. Thus, the more fit organisms would live to reproduce and pass their advantages on to their progeny and consequently slowly alter the species (Darwin 1987, pp. 374–375). Through the next several years, Darwin would develop his principle of natural selection; he found it exquisitely useful in accounting for highly complex anatomical adaptations, especially ones that would not easily yield to Lamarck’s device of use and disuse. However, instincts still seemed more easily explicable by inherited habit.

Problems arose for the habit-instinct conception. Several natural theologians, in the late 1830s and 1840s, insisted that animals exhibited instincts without any knowledge of the purpose of their actions. The caterpillar spun its web without foreknowledge that the purpose was to provide shelter for metamorphosis. Examples such as the caterpillar’s production of a cocoon precluded any intentionally developed habit as source for the instinct. As a result of considering such examples, Darwin began to apply natural selection theory to account for those instincts that habit could not explain. But when he read William Kirby and William Spence’s theologically driven *Introduction to Entomology* in 1843, he was stumped (Kirby and Spence 1818). They described the “wonderful instincts” of different

species of social insect. Soldier bees, for instance, instinctively guarded the nest and sacrificed themselves to protect it; worker bees had the instinct of constructing perfect hexagonal cells to store honey. These kinds of instinct, the authors maintained, could be explained only by divine providence. When Darwin attempted to account for these “wonderful instincts,” he quickly ran into trouble. Natural selection operates to preserve individuals who manifest advantageous traits. But self-sacrifice seems to offer the individual soldier bee no advantage – quite the contrary. Moreover, as Darwin came to appreciate, worker bees and ants were sterile; they did not breed in the first place. In June 1848, after he considered these difficulties, he lamented: “I must get up this subject – it is the greatest *special* difficulty I have met with” (Darwin 1848). In chapter 7 of the *Origin*, Darwin reiterated: the difficulty “at first appeared to me insuperable, and actually fatal to my whole theory” (Darwin 1859, p. 236). In working on that chapter, he hit upon the solution in the nick of time, one that we now more or less have adopted: natural selection works on the whole hive or nest. Those hives that had, by chance, more aggressive individuals were selected over those with fewer. And so the instinct of defensive action by bees, even at the cost of their lives, would gradually evolve over time. Darwin not only had a resolution to the almost “insuperable” difficulty, he offered it also as potent objection to his rival Lamarck (Richards 1987).

Darwin’s solution to the problem of instincts in the social insects had another dividend, a very large one. In the *Descent of Man* (1871), he considered what was distinctive about the human animal. It wasn’t reason, since even his hunting dogs exhibited a modicum of reason. It was moral conscience. If he could not give an account of morality, a wedge would be opened for the return of the deity. Darwin began a construction of a theory of moral behavior, and here his work on the social insects proved crucial. He argued that if advanced animals developed reason sufficient to become reflective, language to communicate needs, and habits to solidify social relationships, then if such proto-human groups also instinctively engaged in cooperation, self-

sacrifice, and mutual care, they would have the advantage over groups that had fewer such altruists. As he wrote in the *Descent of Man*:

It must not be forgotten that although a high standard of morality gives but a slight or no advantage to each individual man and his children over the other men of the same tribe, yet that an advancement in the standard of morality and an increase in the number of well-endowed men will certainly give an immense advantage to one tribe over another. There can be no doubt that a tribe including many members who, from possessing in a high degree the spirit of patriotism, fidelity, obedience, courage, and sympathy, were always ready to give aid to each other and to sacrifice themselves for the common good, would be victorious over most other tribes; and this would be natural selection. (Darwin 1871, vol. 1, p. 166)

Darwinian morality is frequently caricatured as selfish and individually self-aggrandizing. Only the unaware and blinkered critic would so regard it. Darwin himself thought his theory removed “the reproach of laying the foundation of the most noble part of our nature in the base principles of selfishness” (p. 98). The essential grounds for his theory of morality were the social instincts of cooperation, mutual care, and altruism (Richards 1987).

## Instincts After Darwin

As a youth, William James (1842–1910) was enamored of Herbert Spencer’s (1820–1903) evolutionary ideas. He became wary of Spencer, however, through the animadversions of his friend Charles Sanders Peirce (1839–1914). Peirce skewered Spencer’s vagueness and lack of evidentiary foundations for his particular evolutionary considerations, especially in contrast to those of Darwin. James had been introduced to Darwinian theory in medical school through the courses offered by Jeffries Wyman (1814–1874), an early champion of the new theory. That introduction would be reinforced by Peirce and another friend Chauncey Wright (1830–1875). When James himself became a lecturer in the Anatomy Department at Harvard in 1873, he gradually deployed Darwinian theory in his courses. And during this early period in his career, he formulated an evolutionary argument for the

independence of human mind; he debuted the argument in a series of lectures given at Johns Hopkins in 1878.

James’s point of departure in his argument was Thomas Henry Huxley’s (1825–1895) essay “On the Hypothesis that Animals are Automata” (Huxley 1874). Huxley held that mental events were purely epiphenomenal. That is, the brain might be stimulated by sensory impulses that had two effects: (1) a causal train confined to the brain that would produce motor activity and (2) a conscious awareness of phenomena caused by that brain activity. The phenomenal experience might simply be that of, for instance, a black cat and the action to avoid it. But the motor activity of avoiding the cat would be the immediate result only of that causal sequence of brain activity, yielding the motor movement. Consciousness would merely be the passive observer, produced by brain activity but impotent on its own to effect anything. To this epiphenomenal theory of mind, James made a potent objection, which he more carefully spun out in his article “Are We Automata?” (James 1879). James maintained that if consciousness were an evolved trait, then over the course of our gradual descent from ape-like ancestors, that consciousness would become more sophisticated and more finely articulated through natural selection. But natural selection only operates on traits that make a difference to the organism that give it an advantage. If consciousness was naturally selected, it would have to have a use. But if it had a use, then it had to be causally effective in the environment. If the brain were doing all the work, consciousness would be superfluous, and certainly not an evolved trait. Thus, on the premise of the evolution of consciousness, mind had to be effective and had to be independent of the brain (James 1890).

James’s psychology was thoroughly Darwinian, most especially in his theory of emotion, a theory that deployed as a fundamental ground the assumption of human instincts. James proposed a definition of instinct conformable to Darwin’s: “the faculty of acting in such a way as to produce certain ends, without foresight of the ends, and without previous education in the performance.” Though it was usually assumed that

human beings had fewer instincts than brutes, James argued that they were, on the contrary, “more richly endowed in this respect than any other mammal” (James 1887, p. 666). He counted over 30 classes of human instinct (a list large enough to choke the behaviorist John Watson). James wove his conception of instinct into his theory of the emotions. That theory, independently arrived at by the Danish physiologist Carl Lange (hence, the James-Lange theory of emotion), asserted that cognition did not cause emotion, rather that emotion was a direct response to the instinctive wisdom of the body. The bear comes charging after you, instinctively your eyes widen, your body trembles, your heart races, and you start to run. These behaviors, in James’s view, were protective instincts that resulted from millennia of natural selection. Our feeling of this bodily reaction was the emotion. In James’s conception, then, we don’t feel fear and then run, rather we run and as a result become afraid.

### The Behaviorist Reaction to Theories of Instinct

L. L. Bernard (1881–1951), a social psychologist who trained at University of Chicago, surveyed the writings on instinct of over 300 authors publishing between 1900 and 1924. With some amazement, he cataloged 1594 different classes of instinct that had been attributed to men and animals. His study appeared in 1924, the same year as John B. Watson (1878–1958) published a declaration of war against such vague and experimentally recalcitrant subjects as instinct. In his book *Behaviorism*, Watson exclaimed: “Give me a dozen healthy infants, well-formed, and my own specified world to bring them up in and I’ll guarantee to take any one at random and train him to become any type of specialist I might select – doctor, lawyer, artist, merchant-chief and, yes, even beggar-man and thief, regardless of his talents, penchants, tendencies, abilities, vocations, and race of his ancestors” (Watson 1930, p. 104).

Watson’s attack on innate traits represented an about-face. In his first book, *Behavior: An Introduction to Comparative Psychology* (1914), he

framed his study of sensation, instincts, and learning in terms of Darwinian evolutionary theory. His own earlier field research had been on the instincts of the noddy and sooty terns in the Tortugas (Watson 1908). A scant 10 years later, the only inborn responses Watson recognized were three emotional reactions: love, rage, and fear. Out of these elements, very complex edifices of character and behavior could be constructed without recourse to instinct or even conscious mind. Watsonian behaviorism and its reincarnation in Skinnerian conditioning procedures swamped all lingering concerns with instinct in psychology departments in anglophone countries during the first half of the twentieth century. The coffin was nailed shut with the reaction to the eugenic movements in America and Europe, especially the version cultivated by the Nazis in the 1930s and 1940s.

### The Rebirth of Instinct Theory in Ethology

Behaviorists assumed animal and human mind to be void of any preprinted messages, blank slates to be inscribed only by modes of conditioning. This was a doctrine that seemed well-tuned to the American ethos of frontier possibilities, where any little boy might grow up to be president if he had enough gumption and opportunity. In a more hierarchical society, the same presumption would not likely obtain (Richards 2008). In Germany and Austria, evolutionary theory took rather firm root, especially as the result of the impact of Darwinian champions like Ernst Haeckel (1834–1919) and August Weismann (1834–1914). The individual who did the most, however, to adopt and further develop the Darwinian conception of instinct was the Austrian Konrad Lorenz (1903–1989), who, along with the Dutchman Nikolaas Tinbergen (1907–1988), established the discipline of ethology.

Lorenz followed the path of his father to medical school, yet became more occupied by studies of the geese, ducks, and jackdaws that populated his father’s estate just outside of Vienna. His friend and mentor Oskar Heinroth

(1871–1945), a fellow ornithologist, encouraged him to cast his interests within a Darwinian framework. In a paper published in 1932, Lorenz began to refine Heinroth's theory of "drive activities" (*Triebhandlungen*) or what he later would call "instinctive activities" (*Instinkthandlungen*) – using the older, Latinate name to distinguish his conception from psychoanalytic and behaviorist views of drive. In his 1937 paper, "The Establishment of the Instinct Concept," Lorenz discriminated five criteria that would stabilize the concept: (1) fixed behavior would characterize most members of a species; (2) such behavior would be exhibited even by animals raised in isolation from learning; (3) the behavior would usually be more complex than the learning ability of the animal; (4) the actions would sometimes be performed incompletely (*Intentionsbewegungen*) or in inappropriate circumstances (*Leerlaufreaktionen*) – e.g., a kitten stalking a ball of yarn; and (5) the behavior would be rigid and exhibited as fixed reflex chains, not idiosyncratic and flexible actions (Lorenz 1971).

Though Lorenz originally conceived instincts as a chain of reflexes wrought by natural selection, he began to suspect that instinct was more than reflex, rather a drive that sought release, often in inappropriate circumstances. Erich von Holst (1908–1962), a Baltic German and neurophysiologist, in conversations with Lorenz, suggested just the mechanism to explain the behavioral phenomena that his friend observed. Von Holst had discovered endogenous neural centers of rhythmic discharge and coordination, which led Lorenz to hypothesize that animals had reservoirs of response-specific energy gradually accumulating and motivating animals to seek release (Lorenz 1937). It was a theory not unlike that of Freud's notion of libidinal energy that also builds up and seeks release, even in relation to inappropriate objects.

Before the Second World War, Lorenz had begun a collaboration with the comparative psychologist Nikolaas Tinbergen, with whom he would share the Nobel Prize for physiology in 1973, along with Karl von Frisch (1886–1982), for their collective work in the founding of the discipline of ethology. Both spent part of

the war-years in concentration camps, Tinbergen under the Nazis (1942–1944) and Lorenz under the Russians (1944–1948). After the war, they renewed their joint efforts, though they had to work through their political differences first, since, like many German physicians, Lorenz had formally joined the NSDAP (*Nationalsozialistische Demokratische Arbeiter Partei*) (Burkhardt 2005). Typical of the kind of experiments done on animal instinct were those demonstrating what they took to be an "innate releasing mechanism." The three-spine stickleback fish, when confronted with another male with a red belly, or even a crude model with a red underside, would assume the stereotypical threat posture; but when confronting a female with a non-red, swollen belly, it would dance the fixed steps of the mating ritual. A red belly released one kind of instinctive pattern in the male stickleback, while a swollen belly released a very different pattern of behavior (Tinbergen 1951, 1952).

Lorenz's theory of instinct met a hostile reaction from several prominent American psychologists in the 1950s, during the period when behaviorism dominated the profession. Undoubtedly Lorenz's membership in the NSDAP partly accounts for the animus, but the objections caused Lorenz to rethink his conception of instinct. Daniel Lehrman (1919–1972) complained that Lorenz's dichotomous categorization of behavior into learned and innate ignored the genetics of the situation, namely, that any genetic disposition requires internal and external environmental conditions for expression (Lehrman 1953). To make his objection explicit, Lehrman cited the studies of Z. Y. Kuo (1898–1970), who argued against the notion of the perfect isolation experiment. The chick that emerged from the egg and immediately pecked at grain with coordinated movement might well have undergone a kind of conditioning while still sealed in the egg: the head of the embryonic chick, which would be bent over the thorax, would bob up and down with its heartbeat, so the chick might "learn" while still isolated in the egg (Kuo 1929).

In a later monograph, Lorenz met Lehrman's objection in a twofold way. First, he maintained that the concepts of the innate and the learned

were not necessarily antithetical; from an evolutionary point of view, the ability to learn was itself an adaptation naturally selected for, thus part of the phylogenetic program of the species. Second, in the specific case of the chick being condition in the egg to peck at grain, several other species of bird – pigeons, for example – though their heads may have undergone the same bobbing movement in the egg, yet when hatched they didn't peck at grain but shoved their beaks into their parents' mouths. The instincts to peck at grain or to act on the parent were adaptations specific to the kind of animal and thus naturally selected as opposed to having been learned. Lorenz yet conceded that the final shape of behavior was also a function of environmental circumstances but that only the genes carried the specifying information (Lorenz 1965, p. 1).

## The Contemporary Resolution

Three basic positions have been taken on animal instinct. From Descartes through the early work of Lorenz, instincts were understood to be constituted by chains of reflexes that respond to certain environmental releasers. James Watson, B. F. Skinner, Z. Y. Kuo, and other behaviorists in the first part of the twentieth century rather attempted to account for apparently fixed patterns of behavior by appeals to subtle modes of conditioning. The later Lorenz and evolutionary biologists like Ernst Mayr (1904–2005) established the third and most recent conception of instinct, one that recognized the role of genetically determined, species-specific information as well as the environmental conditions required for the implementation of the information. Mayr epitomized this recognition in his proposal that two kinds of programs governed animal behavior, a more closed program and a more open program (Mayr 1974). Closed programs were those in which the releasing mechanisms were controlled by the genome of the species, such as mate recognition and display in many animals. For instance, fertile female *Drosophila* of one species, if reared in isolation and placed among males of several species that displayed to her, would unerringly receive only

the male of her own species. However, freshly hatched graylag goose chicks would follow any object of the right size, if exposed to the moving object (e.g., Lorenz's head while swimming) during a critical period in the young gosling's life. The chicks rapidly learned the stimulus that released the fixed behavior of following. In some species of bird, a chick raised with chicks of a different species would imprint on the foster species and attempt to mate with its members. These cases of imprinting represent a more open program. The mechanisms of instinct, therefore, differ depending on the species of animal and the relative open or closed character of the program. Most behavior biologists today recognize these different instances of instinctual modes of behavior and have thus revitalized the instinct concept.

## Instrumental Blocking

Benjamin R. Eisenreich  
University of Rochester, Rochester, NY, USA

## Definition

Instrumental blocking refers to the ability of a previously trained discriminative stimulus to block the acquisition of a new discriminative stimulus in establishing stimulus control.

## Introduction

Classical conditioning involves the pairing of a neutral stimulus (e.g., a light) with an unconditioned stimulus (e.g., food) that naturally elicits

an unconditioned response (e.g., salivating), such that with repeated pairings the neutral stimulus becomes a conditioned stimulus that can alone elicit a conditioned response. Within the structure of CS-US pairings, different types of learning effects can be observed, one of which is called blocking. Blocking occurs when a previously trained CS-US pairing (e.g., light and food) prevents later acquisition of another CS-US (e.g., tone and food) pairing in eliciting the conditioned response when presented in compound (Kamin 1968). While blocking was first demonstrated within classical conditioning paradigms, it was latter demonstrated to occur within instrumental learning contexts (von Saal and Jenkins 1970).

Instrumental blocking functions much the same manner as blocking phenomena within classical conditioning with some important differences. Firstly, within the instrumental context stimuli are viewed within the framework of available response reinforcer contingencies. Put simply while in a classical conditioning experiment a tone may be learned to signal the arrival of food, in the instrumental context the tone signals the availability of a particular response-reward pairing, for example,

bar-pressing for food. As such, the stimuli are designated as discriminative stimuli that establish stimulus control over the behavior of the organism. For example, if a light signals the availability of food after bar pressing, presentation of the light will cause the animal to engage in greater amounts of bar pressing than in its absence. Similar to classical conditioning, instrumental blocking occurs when one discriminative stimulus is trained and then presented in compound with a new discriminative stimulus (Fig. 1).

Instrumental blocking has been demonstrated to impact both external discriminative stimuli as well as internal stimuli. For example, internal cues such as memory of reward delivery have been used to block acquisition of an external flashing light in establishing discriminative control of maze running (Haggbloom 1981). Likewise, shifts in the reward contingencies prior to compound stimulus training have been demonstrated to prevent blocking acquisition of a new discriminative stimulus in controlling responding. Additionally, both the amount of prior training and saliency of stimuli have been demonstrated to influence the strength of blocking.

**Instrumental Blocking,**  
**Fig. 1** How Instrumental  
Blocking is Tested

|                |                  |             |      |
|----------------|------------------|-------------|------|
|                | Phase 1          | Phase 2     | Test |
| Blocking Group | Light Correlated | Tone+ Light | Tone |
| Control Group  | Light Unrelated  | Tone+ Light | Tone |

In particular, greater prior training with a discriminative stimulus and subsequent reward delivery on the contingent schedule will increase blocking of stimulus control for stimuli paired in compound with the already learned discriminative stimulus. Furthermore, the greater the saliency of the blocking stimulus, the stronger the blocking effect will be on subsequent stimuli presented in compound. Related to saliency, the “surprisingness” or contiguity of the stimuli in signaling the response contingency influences the degree of blocking, with highly contiguous stimuli producing the greatest blocking effect (Haggbloom 1985).

Research into instrumental blocking has resulted in a wealth of theories that describe associative learning as resulting from variations in attention processes to differing associative memory strengths. It has also led to a reconsideration of the once held dichotomy between classical and instrumental approaches in associative learning. In particular, within both contexts the degree to which the previously trained stimulus is at asymptote for controlling behavior directly determines the amount of blocking observed. This has led to theories that specify an upper limit on the degree to which any stimulus can control behavior (Rescorla and Wagner 1972), as well as supported hierarchical accounts of associative learning (Williams 1995).

## How Instrumental Blocking Is Tested

Subjects are placed into an experimental (blocking) and control group and trained to engage in a response and reward contingency, such as lever pressing for food. In phase 1, the first discriminative stimulus (a light) is introduced to both the experimental and control groups. In the experimental condition, the stimulus signals when lever pressing will deliver food, while in the control condition the stimulus is uncorrelated with reward delivery. Thus, when examining the ratio of lever pressing between trials when the stimulus is present vs. absent, there will be greater lever pressing in the experimental group when the light is present than when absent. In phase 2, both

control and experimental groups receive a compound presentation of the trained stimulus and the stimulus to be blocked (a light-tone pairing) that signals reward delivery for lever pressing in its presence. Under this condition, both groups will exhibit greater amounts of lever pressing in the presence of the compound cue than in its absence. After training on the compound stimulus, blocking can be observed by measuring the stimulus control of the second discriminative stimulus when presented in isolation between the control and experimental groups. Within this setup, blocking manifests as a lessened effect of the second discriminative stimulus in controlling responding on the reinforced contingency for the experimental group. That is to say, in the example above blocking of the second discriminative stimulus by the first would result in equal amounts of lever pressing occurring during both the absence or presence of the second discriminative stimulus.

### Synonyms

[Instrumental conditioning](#); [Operant conditioning](#)

### Definition

Instrumental learning is a type of learning in which behaviors are strengthened or weakened by their consequences. It refers to nonreflexive behaviors that are *instrumental* in producing changes to the environment. Instrumental learning differs from Pavlovian (aka respondent or reflexive) conditioning in that it involves voluntary behaviors or actions, both overt and covert. Consequences are typically classified as either reinforcing (which have a strengthening effect on the response) or punishing (which have a weakening effect).

### Introduction

Instrumental learning is a naturally occurring, general process that dictates the conditions under which

behaviors are modified by their consequences. This process differs from Pavlovian conditioning because it involves voluntary behavior rather than reflexes. It was first described by B. F. Skinner (1938) who believed that behavior itself could serve as the object of study and promoted the idea that the best way to understand behavior was to approach it from an experimental and analytical perspective. Skinner referred to these responses as *operants* because they directly operate on the environment. He believed that instrumental learning consists of a three-component system called the *three-term contingency* that includes an antecedent stimulus, the target response, and the consequence (for a detailed review, see Domjan 2015).

## The Three-Term Contingency

### The Antecedent

Antecedent stimuli (aka *discriminative stimuli* or *SD*) consist of salient environmental stimuli that are reliably present when the target response produces a consequence. Over time, the SD comes to signal the specific relationship between the response and the consequence. In other words, the antecedent signals the probability of a specific consequence, given the target behavior. For example, in the presence of a green key light, a pigeon's key peck is highly likely to be reinforced with food. Over time, the SD (or green light) may come to prompt pecking. Common SD stimuli for people include things like streetlights and stop signs that gradually gain control over our driving and braking behavior.

### The Response

Instrumental behaviors are voluntary behaviors, not reflexes. They are defined in terms of the action of an individual. According to Johnston and Pennypacker (1980, p. 48),

*The behavior of an organism is that portion of the organism's interaction with its environment . . . that results in a measurable change in at least one aspect of the environment.*

Put simply, behavior affects the environment, which in turn affects the behavior. It is a reciprocal process that leads to continued adaptation to one's environment. An instrumental behavior can be

described or measured along several dimensions, including count, frequency (count/time), duration, magnitude, latency, and probability. In the laboratory, common responses include lever pressing for rats and key pecking for pigeons, whereas common everyday responses for people include nearly any voluntary behavior that can produce an outcome. They can be as simple as turning on a light switch (the consequence is the light coming on) or as complex as dancing the tango (the consequence may be “not stepping on your partner’s toes”).

**The Consequence**

The consequence of a behavior is the specific change in the environment that is produced by the instrumental response itself. It is the direct outcome of the behavior. Consequences can be described as either reinforcing or punishing and can have a strengthening or weakening effect on the future probability of the behavior. They alter the likelihood that a given response will be repeated in the future under similar circumstances.

Consequences vary along several dimensions such as the type of contingency (or correlation). A positive contingency involves adding a stimulus to the environment following the target behavior. Conversely, a negative contingency involves preventing or removing a stimulus. Another dimension is the type of stimulus involved. Appetitive stimuli are those stimuli or activities that the organism will work to earn. Aversive stimuli or activities are things the organism will work to avoid.

When combined, these dimensional qualities of the consequence produce four basic behavior change procedures (Table 1). Two of these procedures strengthen or increase behavior; two weaken or decrease behavior.

Consequences can be as simple as food or unpleasant noise or as socially complex as attention or criticism. They can also be counterintuitive in that some individuals may work to earn a consequence that another would find aversive (e.g., negative attention or even pain). The important thing to note is that consequences must be defined with respect to the individual recipient. From an evolutionary perspective, one might say that we repeat those behaviors that increase our fitness or improve our immediate situation while forgoing those

**Instrumental Learning, Table 1** Schedules of reinforcement. Four possible outcomes of operant conditioning based on the type of contingency and the type of stimulus involved

|                     | Positive contingency   | Negative contingency   |
|---------------------|------------------------|------------------------|
| Appetitive stimulus | Positive reinforcement | Negative punishment    |
| Aversive stimulus   | True punishment        | Negative reinforcement |

responses that have proven less than beneficial or that led to unpleasant consequences, in the past.

Together, the three terms (Antecedent→Behavior→Consequence) form a functional triadic process that allows antecedent stimuli (*discriminative stimuli or SDs*) to develop control over behavior by signaling a specific response-reinforcer relationship. When a behavior reliably occurs in the presence of an SD, the behavior is said to be under *stimulus control*. In the presence of established SDs, we are more likely to engage in those behaviors that have previously produced reinforcers and less likely to engage in those behaviors with a punishing past.

**Strengthening Behavior**

**Positive Reinforcement**

Positive reinforcement is defined as the contingent occurrence of an appetitive stimulus following the target behavior, such that the future probability of that response is increased. Put simply, when a behavior produces a reinforcer, that response is likely to recur in the future. If an employee invests extra time and effort on a particular project at work and is given a salary bonus for her efforts, we would predict that she would be highly likely to offer similar efforts on future projects.

**Negative Reinforcement**

Negative reinforcement is defined as the contingent prevention or removal of an aversive stimulus following the target behavior such that the future probability of that behavior is strengthened. This process relates to *escape* and *avoidance*

behaviors. Example, many people wear sunglasses in the summer to reduce glare as a result of negative reinforcement. However, some of us wait to put on our sunglasses until we are outside in the sun. If you put your sunglasses on to remove or terminate the glare, you are responding to an *escape contingency*. On the other hand, a few wise individuals will put the sunglasses on before stepping into the sun. For these individuals, an *avoidance contingency* is controlling their behavior.

## Weakening Behavior

### Positive Punishment

Positive punishment is defined as the contingent occurrence of an aversive stimulus following the target behavior such that the future probability of that behavior decreases. If you follow a behavior with a punisher, the likelihood that the behavior will recur in the future is reduced. Although this decrease in behavior may occur slowly over repeated experiences with punishment, behavior typically declines. Of course, long-standing behaviors with a history of reinforcement will respond to punishment more slowly than a behavior that is punished the first time it occurs. If you have a long history of biting your nails, the use of punishment to reduce that behavior may take some time. But the first time you put your hand on a hot stove is likely to be the last time.

### Negative Punishment

Negative punishment is defined as the contingent removal or termination of an appetitive stimulus following the target behavior such that the future probability of that behavior declines. If you follow a behavior with the removal of a valued reinforcer, the likelihood that the behavior will recur in the future will be reduced. There are numerous negative punishment techniques including time-out and response costs. *Time-out* consists of the contingent suspension of the ability to earn reinforcers and is a popular form of punishment among parents. However, time-out is most effective when the time-out location does not offer alternative sources of reinforcement. *Response*

*costs*, on the other hand, involve the loss or removal of a tangible reinforcer. Many teenagers are familiar with the use of response cost contingencies, like having the car keys taken away, following some egregious misbehavior like staying out beyond curfew.

## The History of Instrumental Learning

B. F. Skinner is universally regarded as the father of instrumental learning. His theory of operant conditioning was shaped, in part, by the works of Darwin, Thorndike, and Watson. In his classic paper, *Selection by Consequences* (1981), Skinner describes the analogy between Darwin's (1859) natural selection and the evolution of species and the role of selection through behavioral consequences on the adaptation of the behavior of individuals:

*What we call behavior evolved as a set of functions furthering the interchange between organism and environment. . . Since a species which quickly acquires behavior appropriate to a given environment has less need for an innate repertoire, operant conditioning could not only supplement the natural selection of behavior; it could replace it. (Skinner 1981, p. 501)*

Skinner viewed behavioral adaptation as complementary to the evolution of morphology and structure. To his view, behavioral adaptation could do, for the individual, what Darwinian natural selection could not. His translation of natural selection into selection by consequences through operant conditioning enabled him to argue that the processes relevant to instrumental learning are equally vital to the survival of life on earth. Needless to say, the concepts of operant conditioning and instrumental learning were (and continue to be) shaped by the influences of Darwin's most fundamental concepts.

Skinner was also influenced by E. L. Thorndike who stated that

*. . . Of several responses . . . those which are accompanied or closely followed by satisfaction to the animal will . . . be more firmly connected with the situation, so that when it recurs, they will be more likely to recur; those which are accompanied . . . by discomfort . . . (will) have their connections with that situation weakened, so that when it recurs, they will*

*be less likely to occur. The greater the satisfaction or discomfort, the greater the strengthening or weakening of the bond.* (Thorndike 1911, p. 244)

Eventually, the terms “satisfying” and “discomforting” would be replaced with Skinner’s “reinforcement” and “punishment.” But Thorndike’s law of effect resonated with Skinner and fit with his selectionist view. The law of effect states that a stimulus-response (S-R) association develops between the contextual stimuli and the instrumental response when reinforced. This highlighted the importance of environmental stimuli and their ability to develop control over behavior. Here Skinner found the foundation for the discriminative stimulus, and the three-term contingency was born.

Finally, Skinner was also influenced by Watson’s desire for psychology to abandon the introspective methods of Wundt and structuralism of James and to embrace an empirical science of behavior (Watson 1913). But he disagreed with Watson’s efforts to extend Pavlovian conditioning beyond their original limited scope. Skinner embraced the new American psychology of behavior but perceived Pavlovian conditioning as far too simplistic to explain the complexities of instrumental learning.

The final result was a solid foundation for Skinner’s instrumental learning that would carry behavioral psychology forward. Over the past eight decades, important advances beyond Skinner’s initial laboratory work have shaped the study of instrumental learning.

## Schedules of Reinforcement

As far back as the work of Ferster and Skinner (1957), schedules of reinforcement have been central to the study of instrumental learning. How and when reinforcement is delivered can have profound effects on the strength, rate, and pattern of instrumental behavior. A schedule of reinforcement is basically a rule that describes the specific conditions under which a behavior will be reinforced. The effect on behavior will vary depending on how reinforcers are arranged with respect to timing and effort.

### Continuous Reinforcement

When a single response produces a reinforcer every time, it is referred to as *continuous reinforcement or CRF*. Many examples of CRF schedules are evident in our everyday lives. For example, light switches require only one flip of a switch and the lights go on; the relationship between your steering wheel and the tires on a moving car makes learning to steer easy; pressing the keys on your keyboard produces one letter for every press. Although we can think of examples of CRF, most of our behavior is not reinforced in this manner. Most reinforcers are earned only after repeated instances of behavior, on an intermittent schedule of reinforcement.

### Intermittent Reinforcement

*Intermittent reinforcement* tends to produce more robust behavior because it strengthens both the behavior and its persistence in the absence of reinforcement. CRF, on the other hand, is less likely to produce persistent behavior, and responses will extinguish more rapidly in the absence of reinforcement. Think of that light switch; if we flip the switch and no light goes on, we rarely persist in trying the switch over and over. But if a slot machine in Las Vegas fails to return a big win, we are more than happy to insert more coins. The strength of the occasional payoff keeps us playing as long as we still have coins in our pocket.

Intermittent reinforcement can be arranged in many ways (i.e., different schedules) that can have distinct effects on instrumental behavior. The most common schedules are derived based on two major characteristics:

1. Whether the reinforcers are based on the number of responses (i.e., ratio schedules) or whether there is a delay component prior to an effective response (i.e., interval schedules)
2. Whether the response requirement is fixed or variable

**Fixed-Ratio Schedules.** The fixed-ratio (FR) schedule results when reinforcement depends on a specific number of responses. Whenever this schedule is in effect, the same

number of responses is required to produce the reinforcer. For example, a local phone call usually requires you to press seven buttons to place the call. Whenever you place that same local call, you press the same number of buttons before you get to speak with your friend (or his voicemail). Interestingly, responses that are repeatedly reinforced on an FR schedule become somewhat stereotyped (see Fig. 1), consisting a rapid sequence of responses (called a *ratio run*) followed by a pause after each reinforcer (called a *post-reinforcement pause*). In the laboratory, rats will respond at very high rates on FR schedules, alternating between rapid runs and pauses. The length of the pause is highly correlated with the response requirement: the greater the FR value, the longer the pause. If you watch middle school kids climb flights of stairs, you will often see this break and run pattern with them racing up each flight followed by a brief pause between flights.

**Fixed-Interval Schedules.** A fixed-interval (FI) schedule results when reinforcers are contingent on the first response following a set interval of time; this interval never changes from episode to episode. For example, washing machine cycles are set on FI schedules. The same wash cycle requires a set period of time, followed by a response – opening the washer to remove the clothes. Responding too soon results in clothes that are not yet clean (or spun). FI schedules, like FR schedules, are predictable and, as such, produce a unique response pattern called an *FI scallop*. This pattern is characterized by extremely low (or even zero) responding early in the interval followed by a slow but gradually increasing rate of responding as the end of the interval grows nearer (see Fig. 1). It is believed that the positively accelerating nature of the FI scallop is the result of differential reinforcement of shorter and shorter inter-response times (IRTs). This pattern of behavior is common among college students studying for exams scheduled at regular intervals. Studying behavior is generally low during the early part of the interval, but picks up as the exam draws closer – often ending with a cramming session the night before the exam.

**Variable-Ratio Schedule.** Variable-ratio (VR) schedules are similar to FR schedules, but

they have specific ratio requirements that change from instance to instance, trial to trial. Typically, the VR has a specific value (e.g., VR 30), but this value describes the average number of responses required over the long run. Thus each individual instance of reinforcement may require slightly more or slightly fewer responses than the average. For example, the number of steps from your front door to the closest corner may be an average of 80 paces. However, it could be slightly more or less depending on weather, style of shoe, or any other factor that might influence stride length. But over the long run, there would be an average number of paces (for each person).

How much variability exists within a VR schedule depends on the specific behavior or on the explicit schedule set by the programmer (e.g., slot machines often run on predetermined VR schedules). Variable ratios tend to be very unpredictable from trial to trial and as such produce a relatively high, but steady rate of responding (see Fig. 1). Remember, the absence of any time constraints in a ratio-based schedule allows the individual to respond as rapidly as they wish. Rapid responding brings each reinforcer faster. So it is to the advantage of the individual to respond quickly and efficiently in order to maximize reinforcement. It is this rapid response

**Instrumental Learning, Fig. 1** Idealized patterns of cumulative responses based on the four major schedules of reinforcement. Tick marks signify the delivery of a reinforcer. (Image reprinted with permission from “Operant conditioning: Schedules of Reinforcement,” by Lumen Learning (2017), CC BY-SA 4.0)

rate produced by the VR that allows the gambling house to maximize its profits, at our expense.

**Variable-Interval Schedules.** The variable-interval (VI) schedule occurs when reinforcement is contingent on the first response after an average amount of time elapses. Here too, the interval requirement is specified for each trial, but its duration can vary across occurrences of the behavior. Thus, an FI 30-s schedule will have a delay that is approximately 30-s long before a response is effective. But that interval can be longer or shorter from one instance of the behavior to the next. Again, the range of interval values will vary depending on the specific behavior, but VI schedules typically produce moderate, steady response rates without stereotyped patterns (see Fig. 1). Examples include how often your boss checks your work. If she checks reliably but unpredictably, you are likely to keep the rate and quality of your work at a reasonably high level in order to earn her praise (or avoid her criticism).

### Extinction

Extinction is a unique schedule in which previously reinforced instrumental behavior no longer produces reinforcers. When an instrumental response is no longer effective in producing reinforcement, there can be an initial increase in response rate, called an *extinction burst*, followed by a gradual decline until the response no longer occurs. It can also increase response variability whereby the individual may try variations of the behavior before giving up. How much or how long a behavior persists under extinction before finally being extinguished depends on a variety of factors. Extinction occurs more rapidly after continuous reinforcement (CRF) and more slowly after intermittent reinforcement, known as the *partial reinforcement extinction effect (PREE)*. A number of interesting theories regarding the mechanism(s) of this phenomenon have been suggested over the years (Amsel 1992; Capaldi et al. 1996; Jenkins 1962; Grace and Nevin 2000), but the final answer remains unclear (Domjan 2015).

### Other Schedules

There are many other schedules of reinforcement (such as the differential schedules, compound

schedules, concurrent schedules, mixed and multiple schedules, chain and tandem schedules). Schedules can operate in sequence or in tandem to simulate the most complex of reinforcer arrangements. Such variations are useful in investigating the factors responsible for distinctive patterns of complex instrumental behavior. In 1957, Ferster and Skinner produced the most in-depth compendium of complex schedules to date; it is considered to be the classic seminal work on complex schedules of reinforcement.

**Choice Behavior.** One such area involving complex schedules of reinforcement involves the study of choice-related behavior. Choice can be described simply as the opportunity to select from more than one concurrently available alternative or schedule. Typically, choice behavior is measured by calculating the percent of behavior that we allocate to each alternative, called the *relative rate of responding*.

In 1961, Richard Herrnstein proposed a simple idea: that the relative rate of responding on two alternatives tended to match the relative rate of reinforcement across the two alternatives. It was called *the matching law*, and it simply meant that we allocate our responses in manner consistent with the rates of reinforcement available. A schedule that produces 75% of our reinforcers will receive 75% of our effort. The matching law has been a robust theory and guiding principle for over a half century, and it has produced many procedural derivatives and theoretical extensions and has been employed across a wide range of instrumental behaviors. It has been a source of continued experimentation for decades, and the mechanisms that produce matching have been the focus of prolonged debate (for a review, see Davison and McCarthy 2016).

### Response-Reinforcer Relations

The relationship between the response and the reinforcer is important to the understanding of instrumental learning. Specifically, there are several key aspects of the response-reinforcer (R-R) relation that determine whether learning will be facilitated or inhibited, including (a) timing, aka

temporal contiguity, (b) the nature of the R-R contingency, and (c) the biological relevance between response and reinforcer.

### Temporal Contiguity

The timing of reinforcement is critical to effective instrumental learning. Long delays between a response and its outcome can slow or even inhibit learning altogether. It is thought that the difficulty lies in the ease with which the association between the response and reinforcer is formed. When presented immediately, it is fairly easy to form an association between behavior and its consequence. But with long delays, other events or behaviors may intervene, making an association between the correct response and the reinforcer more difficult.

For many species, bridging stimuli (*aka conditioned reinforcers*) can mitigate R-R delays if they are presented immediately after the required response. This is a well-known method used by animal trainers who rely on clickers or whistles to immediately mark a behavior well done and later provide the reinforcer. Of course, conditioned reinforcers must be trained first by repeatedly pairing the neutral clicker or whistle with food until a Pavlovian association is formed. Then the conditioned reinforcer can be used effectively to bridge a long delay between response and reinforcer. However, immediacy of reinforcement still applies. A bridging stimulus presented at the beginning of a delay can facilitate learning; but if presented at the end of the delay, the same stimulus can block learning (Williams 1999).

### Response-Reinforcer Contingency

Contingency refers to the dependent, causal relationship between the response and the reinforcer. When a behavior directly produces the consequence, the likelihood of instrumental learning is maximal. However, there are exceptions. In cases of accident reinforcement (i.e., the accidental occurrence of an appetitive stimulus immediately after a specific behavior), it is possible for a behavior to change superstitiously. This is common among athletes: we are all familiar with the odd, superstitious behaviors of the baseball pitcher before throwing a pitch or of the golfer

before making a putt. These responses were often accidentally reinforced the first time with a base hit, or a hole-in-one!

**Learned Helplessness.** Another phenomenon related to contingency is our ability to learn about the absence of a contingency. Learned helplessness (Maier et al. 1969) occurs following repeated exposure to inescapable aversive experiences. Later, when presented with impending aversive events, those individuals, who have previously learned that any attempt at escape is useless, fail to learn the new escape behavior. In such cases, learned helplessness may result from incompatible behaviors like freezing, inattention due to a focus on the impending event, or they simply have learned there is no R-R contingency – making the acquisition of escape behaviors even harder. Modern clinicians are aware of the learned helplessness effect among veterans of combat, and among abuse and rape victims, and have investigated neurobiological correlates of both (Hammack et al. 2012).

**Biological Relevance.** In the first half of the twentieth century, proponents of instrumental learning tacitly accepted the notion that any reinforcer could strengthen any behavior. By the 1960s, this *equipotentiality hypothesis* was displaced in favor of a more ethological interpretation that acknowledged biological constraints on the learning processes. This approach, known as the *behavior systems approach*, focused heavily on the biological relevance of the response-reinforcer relation. According to this approach, certain behaviors and reinforcers belong together as part of each behavior system (e.g., foraging and feeding systems, courtship and mating systems, escape/avoidance behaviors and predator evasion systems, etc.). When a behavior and reinforcer belong to the same behavior system, instrumental learning is facilitated. However, when a reinforcer from one system is used to reinforce a behavior from an incompatible system, learning is inhibited. For example, Fantino et al. (1966) demonstrated that lever pressing alone was not easily learned as an avoidance responses in rats; however adding an ethologically appropriate response like running (an escape-relevant behavior) toward the lever allowed lever pressing to be

acquired rapidly. But when the running requirement was removed, even after lever pressing had been acquired, the lever press behavior was lost. The influence of response-reinforcer relevance is key to a thorough understanding of instrumental behavior (for a detailed review, see Timberlake 2001).

## Instrumental Learning and Behavioral Neuroscience

Traditionally, the focus of instrumental conditioning has been between environmental stimuli and behavior. Brain involvement was seen as merely the circuitry of connection for input to become output. Little attention was paid to any direct neural contribution to behavior. As our technology has grown in sophistication, the accessibility of neural contributions to behavior has become more viable as a valid line of investigation. McIlvane and Dube (1997) suggest that seeing neural pathways as important links in a sophisticated behavior chain might lead to insights into the integrated synthesis of the environmental and the behavioral determinants of instrumental behavior.

### Early Brain Stimulation

In 1954, Olds and Milner established reliable responding in rats by delivering electrical stimulation in the limbic septal area of the brain. This finding began the search for the neural pathways and structures associated with both Pavlovian and instrumental learning. Since then, half a century of research supports the idea that neural events (both central and peripheral) are important to behavioral contingencies (for a review, see Guerra and Silva 2010) including the nature of reinforcement and what makes a reinforcer reinforcing.

A more recent example of the effect of peripheral nervous system stimulation on instrumental learning was conducted on the *Aplysia*, a marine snail (Brembs et al. 2002). *Aplysia* feed on seaweed. When they forage, they bite randomly, but only swallow when they obtain seaweed. When a snail swallows seaweed, the esophageal nerve fires. To test whether the esophageal nerve serves as a reinforcer for biting and swallowing, external stimulation of the esophageal nerve was used

following random bites that did not naturally produce swallowing. Results showed that esophageal stimulation increased biting above the rates observed in control snails. Hence, the firing of the nerves associated with swallowing effectively function as a reinforcer for biting.

### Dopamine and Reinforcement

It was long accepted that dopamine, a basic neurotransmitter, is released in the presence of SDs and reinforcers during instrumental learning. Moreover, direct manipulation of the dopamine system can have direct effects of the value of reinforcers: extra dopamine and the value of food and water increase. Dopamine depletion simulates satiation and can impede learning (see Guerra and Silva 2010). Most recently, an investigation of the mechanisms of dopamine mitigation and incentive motivation would change the traditional stimulus-response (S-R) view of the brain-behavior interaction.

**Wanting and Liking.** Berridge and Robinson (2016) discuss the notion that “wanting” and “liking” a reinforcer may not be synonymous. While easily construed as the same concept, the incentive motivation (or “wanting”), that sets behavior in motion, waxes and wanes in step with dopamine increases and decreases. But “hedonic orofacial expressions elicited by sweetness” do not. In other words, even when dopamine is depleted and our motivation to earn a sweet treat is extinguished, we still respond facially to the taste of sweet. Our face says we like it, but our behavior says we don’t want it.

According to Berridge and Robinson (2016), the incentive nature of “wanting” is mediated by midbrain dopamine projections to the forebrain. The strength of the signal depends on dopamine levels and on the strength of the association between the cue and the reward. Dopamine creates a state-dependent increase in “wanting.”

“Liking,” on the other hand, is related the experience of pleasure: all kinds of pleasure including foods, drugs, and even social pleasures. The neural structures for liking are, according to Berridge and Robinson (2016), tiny, neurochemically limited “hotspots” dispersed across the larger limbic system that appear to be independent of the dopamine-based “wanting”

system. For example, the hotspot in the nucleus accumbens represents less than 10% of the entire structure. In humans, these hotspots also occur in the limbic prefrontal cortex and in deep subcortical regions of the brain. The critical issue here is that the two systems appear to be independent, each controlling different aspects of the nature of reinforcement. As their data suggest, neural structures and the role of dopamine are critical to our understanding of what makes a reinforcer effective or not. These results will undoubtedly have profound clinical implications for behavioral interventions in mental health and addiction.

## Instrumental Learning and Comparative Cognition

Within psychological theory and research, the cognitive tree and the behavioral tree have been slowly growing together for over a half a century. Interest in the behavioral correlates of cognition has grown exponentially and extends to memory, categorization, timing, decision-making, problem solving, tool use, and even language. After decades of hostile competition and mutual criticism, cognitive psychologists and behavioral psychologists, along with cognitive ethologists, are now engaging one another and working together to better understand nonhuman animal behavior (for a review, see Wynne and Udell 2013). Two examples illustrate the role of instrumental learning in comparative cognition: the study of behavioral timing and memory.

### Temporal Regulation of Behavior

One great constant in instrumental learning is the influence of time. Temporal regulation of behavior is well established across nonassociative learning, Pavlovian conditioning, and instrumental learning. The degree to which time alone can alter behavior is noteworthy. As such, it begs the question: Can animals keep track of time? And if so, what factors are implicated in the ability to keep track of time? While a complete account has yet to emerge, a host of interesting comparative data has accumulated in the last several decades.

According to Meck and Church (1983), an animal is considered to be timing if the duration

of an event can serve as an SD for them. In fact, sensitivity to duration has been established across a variety of vertebrates (Buhusi et al. 2005; Stubbs 1968; Talton et al. 1999). An illustrative example comes from Fetterman (1995) who demonstrated that pigeons could easily learn to discriminate and respond differently to two key light durations (2 and 10-s). Similarly, Roberts (1981) showed that rats could use different stimulus durations to modulate responding around two distinct schedules (FI 20-s or FI 40-s) with the peak in their responding centered on the point in time when the reinforcers on each schedule would be delivered. Although a resolution regarding the underlying mechanism of timing remains under investigation, there is no doubt that sensitivity to time and temporal regulation of behavior are evident across many species (Lejeune and Weardon 1991).

### Memory

The study of memory has been a shared interest for behavioral psychology and comparative cognition for over a century. The pioneering work on memory and forgetting by Ebbinghaus (1885) fostered a curiosity that extends deep into the modern fields of comparative-cognitive psychology and traditional instrumental learning. Within instrumental learning, the delayed matching-to-sample procedure (Blough 1959) has become the most commonly used and productive method of investigating factors important to short-term memory and forgetting (White 2013).

**DMTS.** In the delayed matching-to-sample (DMTS) procedure, a sample stimulus is presented, and following a delay, a choice must be made between two alternatives. The goal is to match the choice to the sample. Correct matches are reinforced; errors are not. By means of this elegant method, the effects of various factors have emerged by studying the behavior of rats (Cohen et al. 1986), pigeons (Grant 1976), dolphins (Roitblat et al. 1990), primates (D'Amato and Worsham 1974), and humans (Paule et al. 1998).

According to Grant (1976), the longer the delay between sample and choice, the poorer the matching accuracy. Additionally, longer samples facilitate matching performance. These factors may seem obvious, but other influences are less so. For example, extended training with moderate

delays between sample and choice leads to markedly improved accuracy with even longer delays at a later time (Sargisson and White 2001). Other productive memory procedures that have focused on spatial memory as a naturally selected strategy include the Morris water maze (Morris 1984), the radial arm maze, and complex, three-dimensional foraging rooms.

**Morris Water Maze.** Morris (1981) showed that rats could successfully navigate through a tank of opaque water to an invisible platform as long as the distal (room-based) cues remained fixed and could adjust their path when starting from various locations in the tank. He went on, with others, to study the neural correlates of spatial learning (de Hoz et al. 2003; Vorhees and Williams 2006) as well as sex and species differences (Jonasson 2005) and relevant clinical applications (Bromley-Brits et al. 2011) for spatial water maze performance.

**Radial-Arm Maze.** In 1976, Olton and Samuelson designed the first radial arm maze (RAM) to assess memory for places visited. The first radial-arm maze consisted of eight arms (4 ft in length) that radiated out from a central hub. The end of each arm could be primed with small pieces of food, and rats could be evaluated in terms of whether they revisited “empty” arms after having already retrieved the food. Exploration of new arms results in reinforcement; old arms produce extinction. From an evolutionary (optimal foraging) perspective, revisiting an arm wastes valuable energy to the detriment of the animal. The point is that the animal must recall which arms have already been emptied so as to visit only the remaining “loaded” arms. This procedure is a more ecologically valid laboratory simulation of actual foraging than the Morris water maze for many species.

Typical findings show that rats (and other species) learn the maze quickly, in as few as five to ten trials (Olton 1978). Various mechanisms of this high performance have been tested and rejected including olfactory cues like scent marking (Olton and Samuelson 1976) or intra-maze cues like the use of fixed spatial algorithmic strategies (e.g., always go to the arm on the left, Zoldek and Roberts 1978). More recently, Cole

and Shapell-Stevenson (2003) using a 48-arm maze estimated that spatial memory in rats appears to be limited to between 16 and 24 locations. Similar to the Morris water maze, evidence positively suggests reliance on distal cues such as windows or picture frames on the wall; movement of distal landmarks increases errors (Suzuki et al. 1980). But O’Keefe and Nadel (1979) cautioned against the rejection of spatially separated intra-maze cues. Reliance on intra- and extra-maze cues need not be mutually exclusive. Their warning was later supported by Wages (1987) who found no differences in performance between extra-maze and intra-maze stimuli.

The use of radial arm maze studies has led to extensive and broad research in comparative psychology related to spatial orientation, cognitive maps, and the evolutionary mechanisms of maze-related choice behavior (Jonasson 2005). More recently, the influence of neuroanatomical variation effects on radial arm maze performance has been studied in rodents (Crusio and Swegler 2005) and even in humans using virtual reality technology (Goodrich-Hunsaker and Hopkins 2010). The evidence suggests that hippocampal damage increases response latencies and errors in both human and nonhuman subjects, further implicating neural structures as important mediators of spatial navigation and memory.

**Food Caching in Corvids.** Spatial navigation and memory are also critically important to food caching – the storage of food by certain highly adapted species of birds (e.g., corvids like jays and nutcrackers) and rodents (e.g., squirrels). The ability to survive the winter for seed-caching birds like pinyon jays and nutcrackers hinges heavily on their ability to recall the locations of their caches long after they have stored the seeds. Pinyon pine seeds constitute 70–90% of the pinyon jay diet, even in winter when seeds are no longer available (Ligon 1978). Thus, seed retrieval from caches is critical to winter survival (Balda and Kamil 2006). In years with high pinecone production, individual pinyon jays may store up to 26,000 seeds in as many as 20,000 caches (Marzluff and Balda 1992). Given the seasonal changes in landscape topography from cache (in the fall) to recovery (in winter), sufficient retrieval requires specially

adapted or evolved strategies. Many broad mechanisms have been suggested including the use of olfaction, a biological compass, or the use of landmarks or beacons. None of these are mutually exclusive and require independent testing using instrumental procedures.

For example, the classic laboratory study of spatial memory in corvid birds requires special equipment. Kamil and Balda (1985) devised a room that had 180 sand cups ( $12 \times 15$ ), available for caching seeds, mounted flush within the floor. Where the birds stored seeds during three caching sessions in the 18 cups that were available (the other cups were capped) was observed. After storage, the birds were not allowed into the room for 10 days. Following this mandatory retention interval, the birds were then allowed to forage in the room with all 180 cups available. Across several tests, the birds performed above chance levels by relying only spatial memory and not other mechanisms such as olfaction.

More recently, the study of caching behavior has focused on the neural substrates involved in spatial memory and analyses of phylogenetic relatedness between corvid species. Based on comparative brain studies and behavioral differences, de Kort and Clayton (2006) suggest that specific caching adaptations across related avian species may well be the result of convergent evolution, despite a caching common ancestor. Furthermore, these adaptations may have extended beyond simple spatial memory to specialized episodic memory since the content of a caching memory appears to be sensitive to relative degradation risk of individual caches in some species (Clayton and Dickinson 1998). The modern integration and collaboration across behavioral, structural, and evolutionary approaches provides a more thorough understanding of the nature of spatial memory and the adaptations that make each species successful.

## Conclusion

Of course, the aforementioned topics and examples only scratch the surface of the questions being studied by proponents of instrumental

learning and their colleagues. Today, the field of behavioral psychology is more interdisciplinary than ever, with crossovers in comparative cognition, neuroscience, psychopharmacology, and animal behavior. The study of instrumental behavior (both public and private) is benefitting from this multidisciplinary triangulation and collaboration. Furthermore, the experimental analysis of behavior has provided an empirical foundation of principles and laws that are applied to more human endeavors including education, mental health, medicine, and particularly in the treatment of people with intellectual disabilities like autism and Down syndrome.

Skin and its derivative

## Definition

The integumentary system is the largest organ system of human body consisting of the skin and its derivatives.

## Introduction

The integumentary system is a complex organ that forms the external covering of the entire body surface, including the external acoustic meatus, the lateral side of tympanic membrane, and the vestibule of the nose. It consists of the skin, hair, nails, and exocrine glands which is protective against infection, mechanical abrasion, and chemical and radiation injuries. It is the largest organ of the human body, constituting 15–20% of its total body mass. In an average 70 kg person, total weight of skin is about 13 kg and its total surface area is around 2 m<sup>2</sup> (Strandring 2016). It varies in thickness from 1.5 mm to 5.0 mm and the thickness depends on location.

The skin consists of a superficial layer of avascular, stratified squamous epithelium, the epidermis, and a deeper, vascular, dense fibrous tissue, the dermis (Romanes 2015). The skin is separated from muscles and bones by superficial and deep fasciae. The intervening tissue between the dermis and deep fascia is called hypodermis which contains fibro-areolar and adipose tissue.

## Functions of Skin

1. It provides an effective barrier against microbial organisms and forms first line of defense. After antigen interaction, Langerhans' cells of the epidermis provides immunological information to the lymphatic system (Datta 2010).
2. It protects against mechanical abrasion, chemical assault, thermal injury, and ultraviolet radiation damage.
3. It is water-proof due to presence of the stratum corneum. So it prevents loss of body fluid (Datta 2010).
4. It is helpful in Dermatoglyphics.
5. Skin helps in the synthesis of vitamin D under the influence of ultraviolet B (UVB) radiation and also has an important role in synthesis of cytokines, hormones, and growth factors.
6. It controls body temperature mainly by regulating heat loss from the cutaneous circulation and sweating.
7. It relays the sensory information like touch, temperature, pain, and other stimuli from the exterior to the nervous system.
8. It also helps in excretion by excreting secretion from sweat, sebaceous, and apocrine glands (Pawlina 2016).
9. Sexual signaling: Apocrine sweat glands and other skin glands secrete sex pheromones which are important for sexual attraction (Mescher 2013).

## Types of Skin

1. Thin hairy skin: It is present over most of the body surface. It has much thinner epidermis which contains hair follicles.
2. Thick (glabrous, hairless) skin: It is present over palms, soles, and flexor surfaces of the digits.

## Microscopic Structure of Skin

### Epidermis

The epidermis is derived from the surface ectoderm. It is composed of keratinized stratified squamous epithelium in which four layers is found. But in case of thick skin, a fifth layer is also found. From deeper to superficial, these layers are as follow:

- (a) Stratum basale (stratum germinativum): It consists of a single layer of cuboidal to low columnar cells that rest on the basal lamina. It contains the stem cells which give rise to new cells by mitosis which are called keratinocytes. The stem cells undergo mitotic division 2–3 times, after that they move to deeper surface of stratum spinosum, where they lose their mitotic activity (Datta 2010).

These basal cells are connected to each other with the help of desmosome while basal cells are linked to the basal lamina by hemidesmosome (Standring 2016). Melanocytes interspersed in this layer which transferred melanin pigment in the cytoplasm of basal cells (Pawlina 2016).

- (b) **Stratum spinosum (prickle cell layer):** It consists of several layers of large, polyhedral, and closely packed keratinocytes. On light microscopic examination, there are numerous cytoplasmic processes or spines emerge from each keratinocytes, which joined to similar processes of adjacent keratinocyte with the help of desmosomes. Melanosomes either singly or aggregated within membrane-bound organelles are also present in the cytoplasm of keratinocytes.
- (c) **Stratum granulosum:** It consists of 3–4 layers of flattened cells with pyknotic nuclei which is a hallmark of degeneration. Keratinocytes contain numerous keratohyalin granules. These granules are composed of protein profilaggrin which has abundant histidine and trace amount of sulfur. The profilaggrin is the precursors of the protein filaggrin in stratum corneum. Profilaggrin helps in aggregation of the keratin filaments of the stratum corneum. The Golgi-derived lamellar granules are responsible for the release of hydrophobic glycopospholipid material into the intercellular space. This glycopospholipid provides permeability barrier to the epidermis (Standring 2016).
- (d) **Stratum lucidum (clear Layer):** It is present only in thick skin. Some researchers assumed that the stratum lucidum is a part of the stratum corneum. It consists of a thin, translucent layer of flattened eosinophilic keratinocytes held together by desmosomes. Later on, the keratin filaments gradually get deposited in the cell and nucleus and cytoplasmic organelles start disrupting and finally get vanished.
- (e) **Stratum corneum:** It consists of most differentiated cells (corneocytes) of the epidermal layer. The nucleus and cytoplasmic organelles disappear and cytoplasmic matrix is completely filled with keratin filaments.

Under normal conditions, there is a balance between the production of keratinocytes in the stratum basale and the loss of corneocytes from the stratum corneum. But when there is excessive desquamation of corneocytes, leads to dandruff formation on the scalp. In excessive amounts of friction at any sites, this cornified layer becomes thicker which leads to calluses formation.

Normally total epidermal turn-over time is about 52–75 days. In psoriasis, the turnover rates and transit times are significantly shortened around 8 days.

### Cells of Epidermis

1. **Keratinocytes:** Epidermis predominately consists of keratinocytes. These cells take origin from the stratum basale of the epidermis. They convert from polygonal living cells to dead flattened cells which form mature keratin. This process is called as cornification. They also form a component of epidermal water barrier.
2. **Melanocytes:** Melanocytes represent 8% of the epidermis cells (Maranduca et al. 2019). Melanocytes are derived from neural crest cells and during third month of the gestation they migrate as melanoblast at the junction of the epidermis and dermis. They are scattered among the basal cells of stratum basale and produce and distribute melanin into keratinocytes. Each melanocyte supplies melanin to approximately 35–40 neighboring basal keratinocytes. The ratio of melanocytes to keratinocyte is 1:4 to 1:10. In humans, melanin exists into two forms, the brown-black eumelanin and the red-yellow pheomelanin (Del Bino et al. 2018). Normally natural melanin are combination of both eumelanin and pheomelanin. The skin color is decided by the ratio of eumelanin to pheomelanin. The skin color is not related with the number of melanocytes, because it is relatively constant in all skin types (Davis et al. 2019). In black-skin people, the melanocytes are larger, more dendritic as well as contains more late staged melanosomes. In black-skin people,

melanosomes are present throughout the epidermis, including the stratum corneum, and melanin is degraded more slowly due to less lysosomal activity of keratinocytes (Maranduca et al. 2019). Melanin has a protective role against the harmful effects of UV radiations on the nuclear DNA of Stratum basale. It also eliminates harmful free radicals by scavenging processes.

#### Clinical Implication

- (a) **Albinism:** It is an autosomal recessive disorder due to the complete absence or decrease biosynthesis of melanin pigments in melanocytes. They are not able to oxidize tyrosine into DOPA due to agenesis of enzyme tyrosinase (Marçon and Maia 2019).
- (b) **Vitiligo:** It is characterized by localized depigmentation of skin due to loss of ability of melanocytes to produce melanin. It is an autoimmune response to a trigger (sunburn, mechanical trauma, chemical exposures, etc.), which eventually targets melanocytes. It is an autoimmune disorder which manifests as white macules on the skin, especially eyelids, mouth, and hands (Manga et al. 2016).
3. **Langerhans' Cells:** These are dendritic and antigen presenting cells scattered throughout the epidermis. They are derived from common lymphoid progenitor cells in bone marrow and ultimately reach the epidermis via blood stream. When any antigen enters through the skin, the Langerhans' Cells captured and processed the antigen. After that they reach the regional lymph node where the antigen interacts with T-lymphocytes. Langerhans' cell is responsible for delayed (type IV) hypersensitivity reaction in contact dermatitis. Histiocytosis X (Langerhans' cell histiocytosis) is a malignant tumor of Langerhans' cells in which abnormal Langerhans' cells spread in various parts of body and affect them (Pawlina 2016).
4. **Merkel's Cells:** These are embryologically developed from epidermis. These are clear oval dendritic cells which are located in the stratum basale. These cells are bounded to nearby basal keratinocytes with the help of

desmosomes. The cytoplasm contains small intermediate filaments and 80-nm dense-cored neurosecretory granules. They are slowly adapting mechanoreceptors which is activated by hair movement. Merkel cells carcinoma is a very rare and highly aggressive tumor, may be triggered by the Merkel cell polyomavirus. It effects most commonly sun exposed area and spread quickly via lymphatic route.

#### Dermis

The dermis lies beneath the epidermis which has an irregular, fairly dense connective tissue. It is derived from the mesoderm. It is composed of collagen, elastic, and reticular fibers in an amorphous-ground substances which is rich in glycosaminoglycans. The fibroblast is main component of dermis which is a primary source of collagen, elastin, and other proteins. It is composed of two layers: a narrow, outer papillary layer and an inner reticular layer (Fig. 1).

The papillary layer consists of loose connective tissue lies beneath the epidermis with a higher density of cells, a higher content of proteoglycan, and a weaker alignment of collagen fibers (Rippa et al. 2019). It has numerous finger-like connective tissue protrusions, dermal papillae that project into the undersurface of the epidermis which interdigitate with the corresponding recesses of the epidermis, epidermal ridges, or rete ridges (Fig. 1). The dermal papillae contain Meissner's corpuscles which acts as touch receptor. The dermal papillae are rich in the blood vessels and sensory nerve endings.

The reticular layer lies deep to the papillary layer and separated from the papillary by the vascular plexus, rete subpapillare (Rippa et al. 2019). It is thicker and less cellular than the papillary layer. It is composed of the mostly parallel bundles of collagen and elastic fibers which is responsible for the formation of regular lines of tension in the skin called Langer's lines. Surgical skin incision should be given parallel to Langer's lines to achieve best healing with minimal scarring (Pawlina 2016).

**Integumental System, Fig. 1** The diagram showing the organization of skin and skin appendages

## Surface Irregularities of Skin

1. Tension lines/Cleavage lines/Langer's lines: They run longitudinally in the limbs and circumferentially in the neck and the trunk.
2. Flexor lines: These are acquired permanent lines which are found in the vicinity of synovial joints. Along these lines, the skin is thin and attached strongly to underlying deep fascia. These are more prominent on the flexor surfaces of palms, soles, and digits.
3. Papillary (friction) ridges: These are present on the fingers and toes, the palm of the hand, or the sole of the foot. They form ridges which is separated by parallel curved grooves. The apertures of sweat ducts open at regular intervals along the summit of each ridge. A fingerprint is an impression which is formed by the friction ridges of a human finger. This is

unique and not identical in any two individuals and used for medicolegal purposes. The study of these ridge patterns is known as Dermatoglyphics.

## Hypodermis (Tela Subcutanea; Subcutaneous Tissue)

It is layer of loose connective tissue which consists of varied thickness of adipose tissue (Fig. 1). This layer acts like thermal insulator, shock absorber, and storehouse of metabolic energy. It gives passage to nerves, vessels, and lymphatics and also contains striated muscles, such as platysma. The subcutaneous tissue has a very rich vascular supply, so insulin or other drugs is preferably injected into this tissue to promote absorption of drug (Mescher 2013).

## Epidermal Skin Appendages

These are derivative of epidermal epithelium. These include hairs with hair follicles, sebaceous glands, sweat glands (eccrine and apocrine), and nails.

**Pilosebaceous unit:** It consists of the hair, hair follicle, arrector pili muscle, sebaceous gland, and sometimes an apocrine gland.

## Hair and Hair Follicles

Hairs are elongated keratinized structures that develop from the hair follicles. They present over almost the entire body surface except the thick skin of the palms, soles, the flexor surfaces of the digits, lips, nipples, glans penis, prepuce, clitoris, the labia minora, and the inner aspects of the labia majora. The hair density of the face is about 600 per cm<sup>2</sup>, whereas rest of the body has 60 hairs per cm<sup>2</sup> (Strandring 2016). The hair helps in thermoregulation, in case of scalp they protect from external injuries and solar radiations.

**Part of hairs:** Each hair is composed of a shaft, root, and bulb. Shaft projects above the skin which is dead part of hair. The root lying within the hair follicles. The bulb is the enlarged base of the root of hair. The shaft consists of three layers: medulla, cortex, and cuticle.

The medulla is innermost part of the shaft which contains vacuolated (air) cells and melanosomes. The medulla is present only in thick hairs. The cortex is located superficial to the medulla and contains closely packed cuboidal cells. These cells are filled with heavily keratinized cells and melanosomes. The cuticle is composed of keratinized squamous cells which forms the outermost layer of the hair shaft.

**Hair follicle:** The hair follicle is an epidermal invagination either deep (3 mm) into hypodermis or superficial (1 mm) within the dermis which contains hairs. The apical part of the follicle receives the sebaceous gland duct (Fig. 1). The hair follicles are divided into three zones: Infundibulum, isthmus, and inferior segment. The infundibulum is a part between the opening of sebaceous gland duct and opening of hair follicle

at skin surface. The isthmus lies between openings of sebaceous gland duct to the insertion of the arrector pili muscle. The inferior segment is a deeper part which expands to form bulb. The base of hair bulb encloses a bunch of vascularized loose connective tissue which is called dermal papilla.

**Alopecia areata:** It is an autoimmune disease in which there is a non-scarring hair loss without any structural damage of the hair follicle. Hair loss ranges from well-defined patches to diffuse hair loss. The scalp is mostly involved in patchy type hair loss. It affects approximately 2% of the general population. On examination of skin biopsies of the affected skin, it shows a lymphocytic infiltration in and around the hair bulb (Pratt et al. 2017).

## Arrector Pili Muscles

The arrector pili muscles are small bundles of smooth muscle cells. They lie between isthmus of hair follicles and the papillary layer of the dermis (Fig. 1). The sebaceous gland is located between the muscle and the hair follicle (Fig. 1). Therefore, contraction of muscles helps in secretion of the sebaceous gland contents. When these muscles contract, there is erection of the hair shaft to upright position and depression of skin at the site of attachment of muscle to the dermis. This leads to formation of gooseflesh appearance of skin. Arrector pili are absent in some places like facial and axillary hairs, eye brow and eye lashes, nostril hairs, and external acoustic meatuses.

## Sebaceous Glands

These are holocrine glands found in the dermis which secrete oily secretion (Fig. 1). They develop as lateral outgrowths of the outer root sheath of the hair follicle. They are part of pilosebaceous unit because they are associated with hair follicles and the arrector pili muscle. They are located over the whole body except the palms, soles, and flexor surfaces of digits. The meibomian glands at the margins of the eyelids

and ceruminous glands in the external auditory meatus are modification of this gland. In most part of the body, they release their secretory product through the hair follicles. But in some area of hairless thin skin, their ducts open directly on to the skin surface and release sebum, e.g., on the lips, nipples (Montgomery's glands), areolae of the female breast, glans penis, inner surface of the prepuce, clitoris, and labia minora. The number of sebaceous gland is an average of about 100/cm<sup>2</sup> of skin to 400–900/cm<sup>2</sup> in the face and scalp. The total time duration for sebum production from the time of basal cell mitosis to the secretion of the sebum is around 8 days (Pawlina 2016). Sebum acts as the epidermal barrier and pheromone, as well as also helps in the skin's immune system.

At birth, sebaceous glands are quite large, but further during development it regresses, and again, at puberty, its growth and secretory activity increases due to hormonal influence of androgens. At puberty due to androgen influence, there is excessive production of sebum. This disproportionate amount of sebum may become obstructed within the duct and leads to comedone formation. This may get infected and inflamed and leads to acne formation (Standring 2016).

Acne vulgaris: It involves the pilosebaceous unit. It may be either noninflammatory lesions (open and closed comedones) or inflammatory lesions (papules, pustules, and nodules). *Propionibacterium* acne is an important causative agent for acne. Other factor which may be related to acne are family history of severe acne, diet (chocolate and dairy consumption), smoking, occlusive cosmetics, and occupational exposures (Tan et al. 2017).

## Sweat Glands

There are two types of sweat glands in the body:

1. Eccrine sweat glands:-These are widely distributed over most of body surface especially on the forehead, palms, and soles. They are absent from the lips, tympanic membrane, nail bed, nipple, and part of the external

genitalia. Eccrine sweat glands are simple coiled glands which consists of two segments: A secretory segment located deep in the dermis and a long and less coiled duct segment that extends from the secretory segment to the epidermal surface (Fig. 1). It helps in temperature regulation of body by sweating under the influence of cholinergic system. It also acts as excretory organ because it excretes hypotonic watery solution which contains low amount of protein, sodium chloride, urea, uric acid, and ammonia. Eccrine sweat glands may also be activated in emotional condition under control of sympathetic nervous system.

2. Apocrine sweat glands: These are located in few places like the axilla, areola and nipple of the mammary gland, skin around the anus, the external genitalia, the ceruminous glands of the external acoustic meatus canal and the apocrine glands of eyelashes (glands of Moll). They take origin from the same downgrowths of epidermis from which hair follicles arise. Their ducts open in the hair follicle just above the entry of the sebaceous duct. Like eccrine sweat glands, apocrine glands are also coiled tubular glands, but the secretory portion of apocrine glands consists of wider lumen. Apocrine glands become functional at puberty due to development of axillary and pubic hairs. Apocrine glands secrete protein rich and milky fluid which contain pheromones. When secreted, the fluid is odorless, but later on due to bacterial action, it develops an acrid odor. Apocrine glands can be activated by emotional and sensory stimuli only under influence of sympathetic control.

## Nails

Nails are plates of keratinized epithelial cells of stratum corneum on the dorsal surface of distal phalanx which is composed of hard keratin. Each Nail consists of root, body, and free distal border. The nail root is implanted in a fold of epidermis and covers the cells of the germinative zone, or matrix. The matrix consists of stem cells which give rise to new cells at root and after

keratinization these cells are responsible for nail growth. The matrix extends beneath the body of nail as an opaque crescent-shaped white area called as the lunula. The edge of skin fold (stratum corneum) covering the root of the nail is called eponychium, or cuticle. The distal free border of nail is connected to underlying epidermis by hyponychium. The body of nail rest on a nail bed which consists of epithelial cells that are continuous with the stratum basale and stratum spinosum.

The nail apparatus consists of the nail plate, proximal and lateral nail folds, nail matrix, nail bed, and hyponychium (Standring 2016). The perionychium comprises the three nail folds (two lateral and one proximal) and the nearby nail bed.

Nail growth depends on the proliferating capacity of the matrix cells which is different in different digit, age, environmental condition, nutritional status, trauma, and various diseases. Generally, the rate of growth is directly proportional to the length of the digit, therefore it is fastest (approximately 0.1 mm per day) in the middle finger of the hand and slowest in the little finger.

### Clinical Correlation of Nail

1. Clubbing: In clubbing, both anteroposterior and lateral diameter of the nails are increased due to proliferation of connective tissue between nail matrix and the distal phalanx. In normal nail, the angle between the nail bed and the proximal nail fold is approximately  $160^\circ$ , but in the clubbing, there is increase in the normal angle  $\geq 180^\circ$  which leads to increase in convexity of the nail plate. It is an important clinical sign in some disease like bronchiectasis, lung abscess, lung carcinoma, cirrhosis of liver, cyanotic congenital heart disease, etc. (Sarkar et al. 2012).
2. Paronychia: It is an inflammation of the fingers or toes in one or more nail folds (Leggit 2017).
3. Koilonychia: In this condition, nails become spoon-shaped with concave curvature, i.e., central depression of nail with lateral elevation of nail plate. In iron deficiency, 5.4% of the patients shows koilonychia (Razmi et al. 2018).

## Embryology

The skin develops from the surface ectoderm and its underlying mesenchyme. The epidermis and its appendages are developed from the surface ectoderm. The dermis is derivative of mesenchyme and takes origin from three sources: (a) lateral plate mesoderm forms dermis of limbs and body wall, (b) paraxial mesoderm give rise to somites which forms dermis of the back, (c) dermis of the head is derived mostly from neural crest cells (-Sadler 2015). The mesoderm also forms the Langerhans' cells. Neural crest cells form melanocyte which imparts the skin its color, which migrate into the epidermis during epidermal development. Neural crest cells also form specialized sensory nerve endings (Hall 2018). Sebaceous glands, sweat glands, and mammary glands are developed due to epidermal proliferations.

## Vascular Supply of Skin

Cutaneous blood flow is about 5% of the total cardiac output (Standring 2016). It mainly helps in thermoregulation. The epidermis is avascular structure. Mainly blood vessels present in dermis which supply stratum basale of the epidermis and structure present within the dermis. The direct cutaneous, musculocutaneous, and fasciocutaneous systems give blood supply to the skin (Standring 2016). Numerous arteriovenous anastomoses are present in dermis which regulate blood flow through capillary bed and help in thermoregulation.

## Nerve Supply of Skin

1. Motor nerves: These are autonomic nerve fibers which supply blood vessels, arrector pili muscles, and sweat glands.
2. Sensory nerves: These are somatic nerve fibers which carry sensations from the skin by forming various types of sensory nerve endings. These are following:
  - (a) Free nerve endings in the epidermis terminate in the stratum granulosum and carry fine touch, heat, and cold sensations.

- (b) Pacinian corpuscles: They are present in deep dermis and detect pressure changes and vibrations applied on the skin surface (Fig. 1).
- (c) Meissner's corpuscles: They are present in dermal papillae and detect light touch sensation.
- (d) Ruffini's corpuscles: They are present in deep dermis and sensitive to skin stretch and torque.
- (e) Root hair plexuses: They are present around roots of hair follicles and detect movement by tactile receptors.

## Clinical Significance

1. **Atopic dermatitis (Atopic eczema):** It is chronic, pruritic, and inflammatory skin disorder that mostly effects children (Lee et al. 2016). It may relapse.
2. **Seborrheic dermatitis:** It most commonly involves the scalp as well as other seborrheic areas like face, retro-auricular area, and the upper chest. It commonly presents as itchy and flaking or scaling skin. Sebaceous secretions and fungal colonization may be associated with the disease (Borda and Wikramanayake 2015).
3. **Psoriasis:** It is an autoimmune disorder with genetic predisposition. Among the various skin manifestation, plaque-type psoriasis is the most common type (Rendon and Schäkel 2019). The classic clinical presentations of plaque psoriasis is well-demarcated, symmetric, and erythematous plaques with overlying silvery scale which mainly involve the scalp, trunk, buttocks, and extremities (Di Meglio et al. 2014).
4. **Pemphigus vulgaris:** It is an autoimmune disease in which autoantibody targets the intercellular proteins, desmosomes, which is responsible for binding of keratinocytes to each other. The desmosome destruction leads to the disruption of epidermal adhesion, resulting in flaccid blisters (Izumi et al. 2019).
5. **Bullous Pemphigoid:** It is another blistering disease in which linear deposition of autoantibodies along the dermal-epidermal junction

- that target the hemidesmosomes resulting in subepidermal tense blisters (Izumi et al. 2019).
6. **Skin Cancer:** There are three major types of skin cancer: (1) basal cell carcinoma (BCC), (2) squamous cell carcinoma (SCC), and (3) malignant melanoma. The BCC and SCC together are also known as nonmelanocytic skin cancers (NMSC). In general, skin cancers are related with long-standing unprotected exposure to the sun's ultraviolet radiation (UVR). Ultraviolet radiation causes DNA damage and genetic mutations, which result in skin cancer (Narayanan et al. 2010).

BCC is the most common skin cancer type that effects 80–85% of all NMSC. Basal cell carcinoma grows very slowly having good prognosis after surgical removal of the tumor. Superficial BCC mainly effects the most exposed area to sun's UVR and usually presents as a red, pearly translucent, scaly, little wrinkled and ulcerative lesion (Orthaber et al. 2017).

The second most common type of NMSC is SCC and effects 15–20% of all NMSC. People with SCC present a small red, painless nodule, scaling, and thickened patch on UVR exposed skin. Metastasis can occur after disruption of the basement membrane. It is more aggressive than BCC and causes death more frequently than BCC (Orthaber et al. 2017).

Malignant melanoma is the most serious and very rare form of skin cancer which developed in skin melanocytes. The characteristic features of malignant melanoma are (a) asymmetrical shape of skin lesion with irregular border, (b) color variations or multiple colors, and (c) diameter of skin lesion >6 mm (Pawlina 2016). Early stages, melanoma can be managed with surgery alone with good prognosis, but after metastasis, the prognosis is very bad (Davis et al. 2019).

## Intelligence

Thomas R. Zentall  
University of Kentucky, Lexington, KY, USA

---

## Introduction

The question of animal intelligence has long been of human interest dating back to Plato, Aristotle, and Plotinus's notion of *scala naturae*, the natural order of organisms. Later, Romanes, a colleague

of Darwin's, published *Animal Intelligence* (1882) in which he reported collected anecdotes of animal behavior from pet owners and naturalists which suggested that many animals show intelligent behaviors. Romanes's approach tends to ask which human abilities are shared by other animals, but it suffers from the flawed logic exemplified by the cartoon depicted in Fig. 1. Given this bias, it is not surprising that animals that are more similar to us in their sensory, motor, and motivation systems are often judged by us to be more intelligent.

Alternatively, we could take a more evolutionary perspective like that proposed by Desmond Morris (1967) that intelligence is only one means of adapting to rapid environmental change. Other highly successful species such as bacteria and viruses have managed to survive without intelligence, as we know it, by very rapid asexual reproduction, relying on mutations to provide the variability needed to adapt to rapidly changing environments. Furthermore, it can be argued that intelligence per se is not correlated with a high rate of survivability. Consider the relatively small numbers of our ape and, even more broadly, primate relatives. Still more relevant, consider the number of hominid species that have gone extinct.

In general, surprisingly, there is a negative correlation between species intelligence and biological success (as measured by the number of surviving members of a species; Morris 1967).

With the above sobering recognition in mind and because of our interest in our species-centric comparisons, it would be informative to ask about the relative intelligence of other species. The easiest objective potential measure of intelligence would be the volume of the brain of various species. However, brain size is highly correlated with body size so relative brain to body mass or cephalization index would be a better measure of intelligence. Yet even that measure does not take into account the fact that what we consider to be intelligent behavior is regulated by activity in the neocortex (Lui et al. 2011) nor does it consider the fact that species such as birds need to minimize the weight of their brain as they must counteract the effects of gravity. Animals that live in water, however, can afford to have larger brains because the water tends to compensate for the effect of gravity. Thus, a better measure of intellectual potential might be number of neurons in the neocortex. This would appear to be a better correlate of intelligence, were it not for the fact that only mammals have a neocortex. To further

### Intelligence,

**Fig. 1** A visual illustration of the problem of presenting the same test to species with morphological differences

complicate matters, current theory suggests that what we consider to be human intelligence (e.g., the ability to reason) may be an epiphenomenon (Dunbar 1993). Instead, among primates at least, the high correlation between brain size and size of the social group suggests that the neocortex, from which we derive intelligence, evolved to keep track of the social interactions among members of our social group (e.g., those who cooperated with us and those who are freeloaders).

But what about species that do not live in well-integrated groups? One could argue that each species has evolved a brain best suited for its needs within the ecological niche in which it lives. That would mean that it makes little sense to compare the intelligent behavior of other species to our own. And yet, as psychologists we have been doing so for at least the last 150 years because we would like to know how intellectually similar other species are to us.

### Learning to Learn

One measure of intelligence is the degree to which learning is flexible, but we must be careful to assess the learning flexibility of other animals without biasing them by using sensory, motor, and motivational conditions that are most suitable to our own species. Bitterman (1975) has suggested that one can obtain a less biased assessment of the comparative cognitive abilities of species by assessing those abilities relative to the species' own baseline. That is, it may not be appropriate to assess differences in the rate of learning because that will depend on differences in sensory, motor, and motivational abilities. Instead, we might look at differences in an animal's ability to learn *from the experience of learning*. In other words, to what extent can learning facilitate new learning (*learning to learn*)? Then, using the rate of original learning as a baseline, one can determine the degree to which later learning, presumably involving the same processes, is facilitated. That is, how much faster the animal is at learning reversals as the number of reversals increase (i.e., to what extent can they learn to learn?). By this measure there is evidence that rats show more improvement than pigeons, and pigeons show more improvement than goldfish (Bitterman and Mackintosh 1969).

A different approach to learning to learn is to look for improvement in the rate at which discriminations involving *new* stimuli are learned. This phenomenon, known as learning set (Harlow 1949), has been studied primarily using visual discriminations with monkeys, but good evidence for such effects has also been found with olfactory discriminations with rats (Slotnick and Katz 1974). In the limit, learning of a new discrimination, or of a reversal, can occur in a single trial. When it does, it is referred to as a win-stay-lose-shift strategy because stimulus choice is completely controlled by the consequences of choice on the preceding trial. One means of developing such a strategy is to *learn to forget* the consequences of trials prior to the immediately preceding trial. In fact, research has shown that memory for the specific characteristics of the stimuli from prior discriminations does decline as the number of discriminations learned increases (Meyer 1971). Thus, animals approach optimal learning by learning to ignore the effects of all but the most recent experience.

### Relational Learning

According to Mackintosh (1965) animals learn not only which stimulus is associated with reward but also the relation between that response and others, such that with sufficient experience animals can learn about the underlying dimension along which the stimuli vary (e.g., brightness, color, auditory frequency, etc.). Mackintosh's theory provided an account of the paradoxical overtraining reversal effect. If rats are trained, for example, on a brightness discrimination, and are given additional training beyond the acquisition criterion, they are able to reverse the discrimination faster than controls that are trained merely to the acquisition criterion. This finding is of interest because according to more traditional theories of learning (e.g., Hull 1943), the buildup of habit strength should be monotonic with training. According to Mackintosh, however, those animals that were overtrained also learned to attend to the brightness dimension, such that when the discrimination was reversed and the formerly negative stimulus became positive, attention to the brightness dimension allowed the stimulus reversal to be acquired faster for animals that were

overtrained than for those that were trained to criterion.

In the sections that follow, I will examine the evidence that nonhuman animals have the capacity to develop cognitive abilities traditionally viewed as uniquely human. The list of phenomena covered is not meant to be exhaustive, but they are presented to demonstrate the large number of abilities that are not uniquely human. I will start with the ability to categorize stimuli, abilities that represent what humans often consider intelligent behavior.

### **Categorization or Stimulus Class Formation**

Can nonhuman animals learn to classify or group stimuli according to the category to which they belong?

#### **Perceptual Classes**

Pigeons are remarkably adept at responding selectively to photographs of natural scenes, depending on whether the scene involves a human form (Herrnstein and Loveland 1964) or trees or water (Herrnstein et al. 1976), and those objects need not be anything that they might have actually encountered in their past (e.g., underwater pictures of fish, Herrnstein and deVilliers 1980; cars and chairs, Bhatt et al. 1988; paintings by Monet and Picasso, Watanabe et al. 1995). To show that the pigeons did not simply memorize the set of stimuli, Herrnstein et al. presented the pigeon with novel instances of the category and found that they responded to them appropriately.

Although perceptual classes are sorted according to characteristics that they have in common versus those that are absent (consider the class of pictures that contain a human form), there is generally no specific set of characteristics that exemplify all of the members of the class. Even humans who can easily sort members of the class from nonmembers are hard pressed to specify the basis for the discrimination other than the name of the concept itself (person present versus absent). This suggests that the principle underlying this kind of stimulus class formation is complex and difficult to identify.

#### **Equivalence Classes**

A different kind of stimulus class formation involves the arbitrary association of stimuli that have a unique characteristic; what is learned about one or more members of the class transfers to the other members of the class. That is the ability to symbolically represent objects and events. The best example of human equivalence classes is the role that semantics plays in human language. When a word comes to mean the same as the objects that it represents, there is an equivalence relation between them such that what is learned about one member of the class automatically transfers to other members of the class. For example, if experience with dogs and the word dog form an equivalence class, new experiences with dogs will transfer to the word dog, and what one is told about dogs will transfer to the way one interacts with dogs. This powerful aspect of human language allows us to learn about the characteristics of objects without having to experience them ourselves or even observe others experiencing them. That is, one can learn about objects in their absence. Although generally, other animals are not known to communicate about the characteristics of objects not present, there is evidence that animals can form functional equivalence relations (see, e.g., Zentall and Smeets 1996). For example, given that pigeons acquire conditional discriminations (symbolic matching-to-sample) in which a red light and a vertical line are both associated with reinforced choice of a large circle and a green light and a horizontal line are both associated with reinforced choice of a small circle (see Figure 2), it can be shown that the red light and the vertical line form one equivalence relation and the green light and the horizontal line form another. The key to a functional equivalence relation is what is learned about one member of the class transfers without further training to other members of the class. Thus, if one is then trained to choose a white light when presented with the red light and to choose a blue light when presented with a green light, the equivalence relations can be demonstrated by asking if, without further training, the pigeons will choose the white light when presented with the vertical line and will choose the blue light when presented with the horizontal line. Clear evidence for such transfer of training has

### Matching-to-Sample

**Intelligence, Fig. 2** Many-to-one matching training used to show that pigeons will learn that *red* and *vertical* (as well as *green* and *horizontal*) “mean the same thing.” If *red* and *green* samples are now associated with new comparison stimuli, *blue* and *white*, respectively, there is evidence that *vertical* and *horizontal* line are also associated with the *blue* and *white* stimuli, respectively

been found by Urcuioli et al. (1989) (see also Wasserman et al. 1992). Thus, equivalence relations (or symbolic representation), the building blocks of semantics (a critical component of human language), is a form of intelligence for which even pigeons are capable.

### Same/Different Learning

A special case of stimulus class formation is the abstract concept of same/different learning. Given that animals have learned to “match” one set of stimuli (e.g., to select the circle not the cross when presented with a circle and to select the cross not the circle when presented with a cross), will they then be better able to match completely different stimuli (e.g., the colors red and green)? Although

early research suggested that pigeons are not able to show such generalized same/different learning (Cumming and Berryman 1961), later research showed that they have some ability to do so (Zentall et al. 1981; Zentall and Hogan 1976; see also Wasserman et al. 1995; Wright and Katz 2006).

### Memory Strategies

The task most often used to study working or short-term memory in animals is delayed matching-to-sample in which animals such as pigeons are trained to choose the red comparison not the green after seeing a red sample and the green comparison not the red after seeing a green sample. To assess working memory, following acquisition, a delay is inserted between the offset of the sample and the onset of the comparison stimuli, and matching accuracy is assessed as a function of the delay. This procedure generally underestimates the animals’ working memory capacity because not only is the delay a novel unexpected event that results in a generalization decrement, but often the delay is similar in appearance to the intertrial interval which may lead to an “instructional ambiguity” (see Sherburne et al. 1998). If pigeons are given sufficient training with delays, considerably better accuracy has been found (Dorrance et al. 2000).

Of more interest in the study of animal intelligence than the assessment of memory per se is the extent to which animals demonstrate strategies that maintain memory.

### Directed (Intentional) Forgetting

In human memory research, the role of the active maintenance of items in memory has been studied by telling human subjects that they should remember certain items but that they can forget others. When the subjects are later asked to recall all of the items, they typically are able to retrieve more of the items that they were instructed to remember than those that they were told they could forget. The finding has been taken as evidence that memory is an active rather than a passive (automatic) process. But what about other animals? Early

research with pigeons using a cued delayed matching-to-sample task suggested that they too actively retain sample memory (Grant 1981). Specifically, on some trials, a cue to remember was presented during the delay which was followed by presentation of comparison stimuli and reinforcement for a correct response. On other trials, a cue to forget was presented during the delay, and the trial ended following the delay. The problem with this design is there is differential incentive motivation on remember and forget trials because food can be obtained only on remember trials. In a more complex design that controls for motivational effects and that better approximates the human-directed forgetting procedure by allowing the animal to reallocate its memory from the sample to an alternative memory on forget trials in training, better evidence for directed forgetting in pigeons has been demonstrated (Roper et al. 1995). Thus, there is also evidence in nonhuman animals that memory is an active process.

### Episodic Memory

Human memory can be separated into categories according to the degree to which cognitive processes are involved. At the most automatic and least cognitive level is procedural memory, the memory for actions. Perhaps the best example of a human procedural memory that is different from other kinds of memory is learning how to ride a bicycle. It is procedural because although one learns how to do it, it is very difficult to describe how to do it. It is a kind of motor memory that requires trial and error, but even once it has been mastered, it typically defies description.

Declarative memories all involve memories that can be described. In human memory they are referred to as semantic memories because they describe learned facts or rules. When driving one should stop at a red light. The capital of France is Paris. Of course not all memories are purely procedural or semantic. For example, one may be told the posture one should take to hit a tennis ball, but over time it should become procedural, as one becomes proficient at the action.

Episodic memory is a kind of declarative memory that involves personal experience. In principle, to retrieve an episodic memory, one must

“mentally travel back in time.” If one is asked, what did you have for dinner last night, one would think back to the episode to retrieve the answer to the question. It has been argued by some (e.g., Tulving 2005) that humans are the only species that have episodic memory. Furthermore, there is some controversy as to what one should accept as evidence for episodic memory in a nonverbal organism. For example, Tulving (1972) originally proposed that an episodic memory should include the *what*, *where*, and *when* of an experience. Using this criterion, Clayton and Dickinson (1999) showed that western scrub jays that cached peanuts and wax worms (what) on one side or the other of an ice cube tray (where) learned that their preferred wax worms would be edible after 1 day but after 4 days only the peanut would be edible (when; see also Babb and Crystal 2006, for a similar finding with rats).

Alternatively, it has been argued that the *what*, *where*, and *when* of an experience are not sufficient because certain rule-based memories (e.g., historical facts) can satisfy those criteria. Instead, it has been argued that better evidence for an episodic memory would be the retrieval of a memory for a past event when, at the time of the episode, there would have been no expectation that a request to remember the event would be made (Zentall et al. 2001). For example, in the classic example, what one had for dinner last night typically would not be something that would have been encoded in memory for later retrieval. Instead, to retrieve that information, typically, one would have to “mentally travel back in time.” Stated otherwise, episodic memory involves the retrieval of events that have been incidentally encoded. According to this definition, evidence for episodic memory might be demonstrated if after being trained on a conditional discrimination (e.g., to choose the vertical line when the sample was yellow but choose the horizontal line when the sample was blue) animals were unexpectedly asked to recall the location of the comparison line last pecked (Singer and Zentall 2007; see also Zhou et al. 2012). The results of such research suggest that pigeons and rats have some ability to retrieve memory of episodes unlikely to be encoded as rules.

### Prospective Memory Processes

Traditionally animal memory has been viewed as a rather passive process. According to this view, sensory events can leave a trace that may control responding even when the event is no longer present (Roberts and Grant 1976). However, there is evidence that animals can also actively translate or code the representation of a presented stimulus into an expectation of a yet-to-be-presented event (Honig and Thompson 1982).

To get a feeling for what a prospective memory process might be like, imagine a pigeon trained on a delayed matching task with vertical and horizontal line sample stimuli and red and green comparison stimuli. One can then ask what is it that the pigeon remembers during the delay prior to the presentation of the comparison stimuli. The most obvious memory would be of the line that was presented as the sample stimulus, but it is also possible that the pigeon has translated the sample into a response intention (e.g., to choose the red comparison stimulus at the end of the delay). A response intention would be an example of a prospective memory. The ability to use expectations, or prospective coding processes, has important implications for the cognitive capacities of animals. If the expectation of a stimulus, response, or outcome can serve as an effective cue for comparison choice, it suggests that animals may be capable of exerting active control over memory, and, in particular, it may suggest they have the capacity for active planning. Although most research has found that pigeons remember the sample that was presented prior to the delay (Urcuioli and Zentall 1986), there is some evidence that under the right conditions pigeons can be induced to code memories prospectively (e.g., Jackson-Smith et al. 1993).

- i. *The differential outcome effect.* Strong evidence for a prospective memory process in animals is the differential outcome effect. This effect can be shown most simply in the acquisition of a conditional discrimination. If, for example, a correct response following one sample is followed by one kind of outcome (e.g., food) and a correct response following the other sample is followed by a different

outcome (e.g., water), acquisition of the conditional discrimination by rats is faster than if both correct responses are followed by food or by water (Trapold 1970). Furthermore, if one inserts a delay between the offset of the sample and the onset of the comparison stimuli, pigeons that have been trained with differential outcomes show less of a decrement in accuracy with increasing delays than if the outcomes are nondifferential (Peterson et al. 1980). Finally, and most convincingly, there is evidence from transfer-of-training experiments that in the absence of other cues, such as an appropriate sample stimulus, outcome anticipations can serve as sufficient cues for comparison choice. That is, if the original samples are replaced by other stimuli associated with the same differential outcomes, positive transfer has been found (Edwards et al. 1982; Peterson 1984). What is important about these experiments is that pigeons are making their choice based not only on their memory of the sample presented on the current trial but also (and in the case of the transfer of training experiments, exclusively) based on their expectation of the outcome that they anticipate will follow.

- ii. *Future planning.* One of the hallmarks of human cognitive behavior is our ability to consciously plan for the future. Although other animals appear to show similar behavior (they build nests and cache food for the winter), this behavior is clearly under genetic control. That is, if we had some way to ask a nest-building bird why it is building a nest, it would likely reply that it just has an urge to do so with little expectation of later use. Trial and error learning would not be reliable enough for such an important behavior. But even if learning was involved in a behavior that appeared to prepare the animal for the future and an animal could articulate why it was engaged in the behavior that will lead to a future reward, how would one distinguish between future planning and a long delay of reinforcement?

Suddendorf and Corballis (1997) have suggested that the behavior indicative of future planning must occur in the absence of the relevant

motivation. For example, will a sated animal work for food that it does not currently need but it has learned that it will likely need at a later time? In a review of the future planning literature, Roberts (2002) has suggested that monkeys do not appear to plan for the future. He cites several examples, including the anecdote that when monkeys in a zoo are fed once a day, after they have eaten, they often throw away the remaining food rather than keep it in anticipation of hunger later in the day.

However, evidence for future planning has been suggested by research with western scrub jays by Raby et al. (2007). These birds, which cache food for future use, learned that unpredictably, they would either spend the night in a side compartment in which in the morning they would find one kind of food (peanuts) or in a side compartment in which they would find a different kind of food (kibble). On test trials, the night before, they were allowed to first eat the provided food in a central compartment and then cache some of the remaining food in either side compartment. When they were given peanuts in the central compartment, they tended to cache the remaining food more in the kibble compartment, and when they were given kibble, they tended to cache the remaining food more in the peanut compartment. That is, in the absence of a current motivation for food, they cached the remaining food in the compartment in which they would not find that particular food in the morning. Thus, they showed the ability to anticipate where the current food would not be present and cache the current food there.

Although some animals appear to have the ability to plan for the future and also show evidence of episodic memory, it is clear that we humans engage in such activity to a much greater extent. In fact, it can be argued that we humans spend more time occupied in recovering past memories and in planning the future than we spend engaged in the present (Farb et al. 2007). One of the goals of meditation is to encourage humans to focus on the present, but in the absence of current task-related activities, it is not always easy to do (Chan and Woollacott 2007).

## Navigation

We humans are not known for our navigational skills, which explains our use of external supports such as compasses, maps, and global positioning devices. Other species, however, are able to navigate seasonally over hundreds, even thousands, of miles using a variety of mechanisms including magnetic fields, chemical gradients, and star patterns. Homing pigeons, unlike other species, are central place foragers, and they sometimes travel great distances in search of food and find their way back. Research suggests that the navigational tools that they use are complex including where the sun is in the sky, magnetic fields, and possibly odors (Wiltschko and Wiltschko 2003). They also use both natural and man-made landmarks (Lipp et al. 2004).

From a cognitive perspective, an interesting human ability is the use of cognitive mapping, the ability to imagine the pathway one should follow to get to a destination. With humans, one can study cognitive mapping by asking subjects to describe the route that they would follow to get to a goal. Alternatively, a nonverbal indirect means of assessing the ability to form a cognitive map can be obtained by asking if a subject can get to a familiar destination by means of a novel path when the familiar path is blocked. The ability to form a cognitive map suggests the knitting together of landmarks one has experienced, such that the relation among those landmarks can serve as the basis for understanding the direction one should take to arrive at the destination along a path that has never been taken. The idea is landmarks are needed to *form* a cognitive map, but they should not be needed to *use* a cognitive map.

Some animals have the remarkable ability to navigate in the absence of landmarks or other external cues. For example, desert ants use path integration or dead reckoning which involves the representation of direction and distance one has traveled from a starting point to food such that one can take a more direct path back to the nest than the often circuitous route taken on the way out. This ability can be demonstrated by displacing the ant after it has found food and is ready to return to its nest. When it is released, it sets off along a path

parallel to the appropriate path. Then it begins searching at an appropriate distance, had it started out from the location from which it had been displaced (Collette and Graham 2004). The distinction between path integration and cognitive mapping has been a point of controversy. However, under conditions that cannot be accounted for with either landmark use or path integration, there is evidence for the development of a simple cognitive map in dogs (Chapuis and Varlet 1987) and rats (Singer et al. 2007). That is, Singer et al. found that under conditions that would be unfavorable for the formation of a cognitive map but should be satisfactory for path integration, rats do not systematically choose the appropriate novel path, whereas when conditions are more favorable for the formation of a cognitive map, rats are more likely to choose the appropriate path.

## Counting

The term counting is used to describe what humans do when they assign numerical symbols to objects in a set. To qualify as counting, the order of the symbols is fixed (i.e., 1, 2, 3, . . .), but the symbol given to each object is not fixed, and the last symbol is also similar to the name of the whole set (e.g., the fifth object and five objects). There is evidence that chimpanzees can be trained to assign Arabic numerals to quantities of objects and even combine Arabic numerals demonstrating simple addition (Boysen and Berntsen 1989; see also Pepperberg 1987); however, most research with animals has involved numerical competence, a simpler process that might be differentiated from human-like counting by the ability to respond appropriately to the presence of a specified number of objects presented either simultaneously or successively (Boysen and Capaldi 1993).

An excellent review of the animal counting literature was provided by Davis and Memmott (1982), who concluded that “although counting is obtainable in infra humans, its occurrence requires considerable environmental support” (Davis and Memmott, p. 566). In contrast, Capaldi (1993) concluded that under the right conditions,

animals count routinely. In simple but elegant experiments, Capaldi and Miller (1988) demonstrated that following training, rats can anticipate whether they will get fed or not for running down an alley depending solely on the number of successive times they have run down that alley and found food or the absence of food on successive earlier trials (see also Rayburn-Reeves et al. 2010). That is, numerical competence is easier to demonstrate in animals if the events have importance to the animals (e.g., the number of times it has obtained food).

The difference in the conclusions reached by Davis and Memmott (1982) and by Capaldi and Miller (1988) has general implications for the study of intelligence in animals (including humans). As it turns out, the context in which one looks for a particular capacity may determine whether one will find evidence for it. Because we, as human experimenters, devise the tasks that serve as the basis for the assessment of intelligence, we must be sensitive to the possibility that these tasks may not be optimal for eliciting the behavior we are assessing. That is, much of our view of the evolutionary scale of intelligence may be biased in this way by species differences in sensory, response, and motivational factors.

## Reasoning

Reasoning can be thought of as a class of cognitive behavior for which correct responding on test trials requires an inference based on incomplete experience. One example of human reasoning is the transitive inference task (Piaget 1928). In its simplest form, transitive inference can be described as: if A is greater than B ( $A > B$ ), and B is greater than C ( $B > C$ ), then it can be inferred that A is greater than C ( $A > C$ ), (where the letters A, B, and C represent arbitrary stimuli). It is assumed that a correct response requires that an inference be made about the relation between A and C based on their common relation to B. With this version of the task, there is the possibility of a non-relational solution based on the fact that although A is greater than something, and B is greater than something, C is not greater than

anything. Thus, A must be the correct response. To avoid this non-relational solution, sometimes referred to as an end-point effect, experimental researchers typically use a task that involves four propositions:  $A > B$ ,  $B > C$ ,  $C > D$ , and  $D > E$ , and the test involves the choice between B and D, each of which is sometimes greater and sometimes lesser.

When the transitive inference task is used with animals, there is another problem. With humans, the task is presented verbally as relationships (e.g., Alice is taller than Betty, and Betty is taller than Carol – who is taller Alice or Carol?). That is, the stimuli are all presented relationally and do not have any absolute characteristics, such as size. Thus, the height of the stimuli (children?) is not specified, whereas with animals the stimuli must have absolute value (e.g., they must be presented visually). But if the stimuli differ in observable value, a correct response can be made without the need to make an inference because clearly B would be greater than D.

McGonigle and Chalmers (1977) suggested that a nonverbal relational form of the task could be represented by simple simultaneous discriminations in which one stimulus is associated with reinforcement (+) and the other is not (–).  $A > B$  can be represented as  $A+B-$ ,  $B > C$  as  $B+C-$ , and so on. With four propositions an animal would be exposed to  $A+B-$ ,  $B+C-$ ,  $C+D-$ , and  $D+E-$ . A is always positive, and E is always negative, but B and D, stimuli that were never paired during training, would share similar reinforcement histories. If animals order the stimuli from A is best to E is worst, then B should be preferred over D.

Findings consistent with transitive inference have been reported in research with species as diverse as chimpanzees (Gillan 1981), monkeys McGonigle and Chalmers (1977), rats (Davis 1992), and pigeons (Fersen et al. 1991). Before concluding that all of these species are capable of transitive inferences, one needs to ensure that there is not a simpler account of these findings. For example, Couvillon and Bitterman (1992) have suggested that the particular sequence of reinforced and nonreinforced responses to the target stimuli B and D may account for the preference for B. In training it may be that there were

more reinforced responses to B or more non-reinforced responses to D. To control for this possibility, Lazareva and Wasserman (2012) provided pigeons with a large amount of additional training with the  $D+E-$  pair and still found a preference for B. A second, non-inferential account was proposed by Fersen et al. (1991) who suggested that in a simultaneous discrimination, some of the value of the positive stimulus ( $S+$ ) will transfer to the negative stimulus ( $S-$ ) with which it is paired. Then because the always positive A stimulus in the  $A+B-$  pair has more value to give to B than the sometimes positive C stimulus (in the  $C+D-$  pair but sometimes negative C stimulus (in the  $B+C-$  pair has to give to D, B will be preferred over D (see also, Steirn et al. 1995). Weaver et al. (1997) tested this hypothesis with pigeons by using a procedure in training that equated the values of the A, C, and E stimuli. When they tested the BD pair, they still found a preference for B over D. Thus, pigeons have shown transitive inference results that to date are not easily accounted for by simpler mechanisms (but see Vasconcelos 2008).

## Perspective Taking

Sometimes called theory of mind, taking the perspective of others means one understands what others do and do not know. In the three mountain problem, for example, a child is placed on one side of a three-dimensional display with a doll on the other side, and the child is asked what the doll sees. Young children respond that the doll sees whatever they themselves see, but older children report what one would see from the other side of the display. To demonstrate perspective taking in animals is more complicated because in the absence of language, perspective taking must be inferred from other behavior.

Hare et al. (2001) attempted to study perspective taking by exposing chimpanzees to a food competition task in which a subordinate chimpanzee could see where food was placed and could also see either that a dominant chimpanzee did or did not see where the food was placed. They reported that the subordinate chimpanzee was

more likely to get to the food first if it could see that the dominant chimpanzee did not see where the food was placed. The presumption was that the subordinate got to the food because it knew that the dominant did not know where the food was placed. It is possible, however, that if the dominant chimpanzee knew where the food was placed, it would be staring at the food, and the subordinate chimpanzee would tend to avoid the location where the dominant chimpanzee was staring. That is, the dominant chimpanzee provided a cue at the time the subordinate chimpanzee was released.

## Self-Recognition

Recognizing the image of oneself in a mirror is an ability that was traditionally viewed as a human quality until in a carefully controlled experiment Gallup (1970) demonstrated that chimpanzees also have that ability. Gallup developed what has been referred to as the mark test for self-recognition. After considerable exposure to a mirror, a mark is placed on the face of the chimpanzee, and when the mirror is reintroduced, the chimpanzee passes the mark test by making contact with the mark that can only be seen in the mirror. Mirror-directed mark exploration appears to occur generally in the great apes (orangutans and perhaps also in gorillas) but not in monkeys even with extensive mirror experience (Gallup and Suarez 1991). However, more recently evidence has been found for self-recognition in dolphins (Reiss and Marino 2001), elephants (Plotnik et al. 2006), and magpies (Prior et al. 2008). Thus, self-recognition appears to occur in several non-primate species also thought to show other kinds of cognitive skills.

## Imitation

According to Piaget (1951) perspective taking has been implicated in the ability to imitate the behavior of another. But imitation can refer to a broad range behavior much of which would not necessarily involve perspective taking. For example, the finding that a sated animal will begin eating

again if placed in the context of another animal that is eating would more parsimoniously be considered an example of behavioral contagion (Zentall 1996). And it is possible that the mere presence of another animal may increase the arousal or motivation of a focal animal leading to the more rapid acquisition of a target response such as pressing a lever (social facilitation, Zajonc 1965). Furthermore, in some cases observation of a conspecific performing a response may demonstrate the affordances of the environment (e.g., the downward movement of a lever is followed by the arrival of a reward, learned affordances (Klein and Zentall 2003).

The two-action procedure was developed to provide a control for these alternative forms of copied behavior (Zentall et al. 1996). In the two-action procedure, observers are exposed to a demonstrator performing a response in one of two topographically different ways (e.g., a bird stepping on a treadle or pecking at the treadle). Imitation is said to occur if the observer performs the response in the same way that it has seen it performed (Akens and Zentall 1996). There is even evidence that pigeons can imitate a sequence of two responses, operating a treadle (by stepping or pecking) and pushing a screen (to the left or to the right; Nguyen et al. 2005), an example of what Byrne and Russon (1998) refer to as program-level imitation.

Can one conclude from this evidence for imitation that these observer birds can take the perspective of their demonstrators? Although logically one could argue that perspective taking is likely involved, children do not develop the ability to take the perspective of another until they are 5–7 years old, yet they are able to imitate others at a much earlier age. Thus, although cognitively interesting, imitation may not provide evidence for the kind of cognitive behavior implied by perspective taking.

## Tool Use

When we consider tool use, we tend to think of it anthropocentrically, and examples that come to mind involve primates that have opposable thumbs. Thus, there is evidence that chimpanzees

use tools when they collect a flat rock and use a second rock that can be held in the hand to break the shell of a nut by hitting it as it rests on the flat rock (Boesch and Boesch 1990). Similarly, when a chimpanzee fashions a flexible stem from a plant and chews on the end to spread it out before sticking it into the hole in a termite hill, it is using a tool to collect termites to eat (Fay and Carroll 1994). Similarly, when a sea otter swims to the bottom to collect a rock and a sea urchin, and at the surface hits the sea urchin against the rock placed on its chest, it also qualifies as tool use. Less obvious is the sea gull flying with a clam to drop it onto rocks to break open the clam (Cadée 1989). Although the tool (the rock) is not actually manipulated, some would argue that it functions as a tool because it consists of an external object used to help the animal gain a desired end (Beck 1980). More compatible with what we consider to be similar to human tool use is the use of twigs by New Caledonian crows to pry grubs free from holes in dead logs (Hunt 1996).

However, when considering intelligent behavior, we try to distinguish between tool use that might be genetically predisposed or species typical and tool use that has been arrived at through problem-solving or reasoning. Weir et al. (2002) found that New Caledonian crows can learn to use a bent piece of wire to hook the handle on a small food bucket that has been placed at the bottom of a tall cylinder. Such a task would not have been encountered in nature nor would bendable wire hooks have been available with which to retrieve the bucket. Even more remarkable, when the bent wire was not available, one crow managed to bend the wire into a hook that could then be used to retrieve the bucket.

## Language

Many species communicate naturally. They give calls to warn others of the presence of predators (Charnov and Krebs 1975), to attract a mate (Ballentine et al. 2004), and to defend their territory (de Kort et al. 2008). Honeybees are even able to communicate about the location and amount of resources that they have found (Gould 1974), and vervet monkeys are able to

communicate about the *kind* of predator that they have seen, an ability that indicates what kind of evasive action their troop-mates should take: climb high in a tree if the predator is a large cat, hide in the bushes if the predator is a bird of prey, or rear on their hind legs to locate the danger if the predator is a snake (Seyfarth et al. 1980). But humans are the only species that naturally acquire a complex form of communication known as language.

What makes a language different from communication is it can refer to objects and events not currently present, and it combines symbols in complex ways that makes the order of the symbols important (the quality of syntax or grammar) and production (the ability to communicate about things for which one does not already have a symbol, e.g., a chimpanzee named Washoe signing “water-bird” upon seeing a swan).

Although humans are the only species that has naturally developed what we refer to as language, several projects have trained chimpanzees in various forms of symbol use that approximate language. The earliest of these was using American Sign Language with Washoe (Gardner and Gardner 1998), and that project demonstrated that she was able to learn a large vocabulary. A different approach using plastic symbols for words focused on objects, their properties, and object categories (e.g., same/different) was developed by Premack and Premack (1983). A third project introduced syntax, a quality thought to be missing from the other two projects (Savage-Rumbaugh et al. 1998; see also Herman et al. 1984, using dolphin subjects). Interpretation of the results of these projects as examples of language acquisition remains somewhat controversial (see e.g., Terrace 1979). At the very least, however, those projects have forced us to better define what it is that makes language unique.

## What Animals Can Tell Us About Suboptimal Human Behavior?

Certain behaviors may not qualify as intelligent or rational but because they are prevalent in humans and have been attributed to the unique experiences of humans, if they can be found in other species,

they have implications for the understanding of human biases and heuristic behavior.

### Cognitive Dissonance

One of these biases has to do with a phenomenon widely studied in humans known as cognitive dissonance. Cognitive dissonance is the discomfort that comes when there is a discrepancy between one's beliefs and one's behavior. For example, if one believes that one should tell the truth, one is likely to feel dissonance on occasions when one fails to do so and one can resolve that dissonance by finding reasons to justify lying. Cognitive dissonance can be attributed to the need humans have to be considered consistent. Cognitive dissonance has been considered to be a form of social intelligence (Festinger 1957), and it is difficult to imagine how one would go about studying it in animals.

One approach would be to examine a form of cognitive dissonance called *justification of effort* (Aronson and Mills 1959). Justification of effort is the added value that one often gives to rewards depending on the effort required to obtain the reward. For example, rewards that are difficult to obtain are often valued more than the same rewards that are easy to obtain. One way to study this effect in animals is to require an animal to work hard for Signal A for a reward and not so hard for Signal B for the same reward and then ask the animal which signal it would prefer A or B. Clement et al. (2000) found evidence for such an effect in pigeons which showed a preference for stimuli that they had to work harder to obtain (see also Kacelnik and Marsh 2002). But is there a simpler explanation?

Zentall and Singer (2007) suggested that this choice behavior may result from the contrast between the relatively negative emotional state of the organism at the end of the greater effort and presentation of the reinforcer (or upon presentation of the signal for reinforcement). Thus, contrast may provide a more parsimonious account of the pigeons' choice behavior. There is also evidence that contrast plays a role in the justification of effort effect found in humans (Alessandri et al. 2008; Klein et al. 2005; Lord 1992). Could contrast also play a role in the more

general cognitive dissonance phenomenon found with humans?

### Suboptimal (Gambling-Like) Behavior

When humans buy lottery tickets or operate slot machines, they are engaging in suboptimal behavior because the return on the bet is typically less than the bet. Humans justify their decision to gamble by describing it as a source of entertainment, and although it is difficult to show that gambling is not entertaining, if one were to remove the monetary aspects of the gamble, it is not as likely that those people would be willing to engage in the activity.

An alternative approach to the question of whether entertainment is the basis of human gambling behavior would be to ask if other animals are as likely to engage in suboptimal gambling as humans. According to optimal foraging theory (MacArthur and Pianka 1966) generally, animals have been selected by evolution to make optimal choices (so they would be more likely not to engage in gambling behavior).

This hypothesis has been tested in a number of experiments, and results quite similar to those with humans have been found. For example, pigeons were given a choice between two alternatives: the gambling alternative in which there was a 20% chance of receiving a green light that predicted they would receive ten pellets of food (the "jackpot") and an 80% chance of receiving a red light that predict they would receive no food (the loss) and the nongambling alternative in which they received a signal that they would always receive three pellets of food (Zentall and Stagner 2011). The results indicated that the pigeons showed a strong preference for the gambling alternative even though they would have received 50% more food for choosing not to gamble.

The mechanism responsible for this suboptimal behavior appears to be the fact that the signal for nonreinforcement fails to gain the inhibitory value that one would expect (Stagner et al. 2012). Thus, the ten-pellet signal for reinforcement is judged to be better than the three-pellet signal for reinforcement, irrespective of the lower frequency of its occurrence. A more direct test of this hypothesis was conducted by Smith and

Zentall (2016) who had pigeons choose between a 50% chance of receiving a signal for 100% reinforcement and a 100% chance of receiving a signal for 100% reinforcement. Once again intuition would predict that the alternative that provided reinforcement 100% of the time should be preferred but given that the two signals for reinforcement, once they occurred, predicted reinforcement equally, the pigeons were indifferent between them. This account appears to be consistent with research with humans that has found that gamblers overvalue wins in spite of their low probability of occurrence, and they give too little negative value to their losses, in spite of their high probability of occurrence (Blanco et al. 2000). These results suggest that gambling behavior is likely to have a simple biological basis and although social and cognitive factors may contribute to human gambling behavior, the underlying mechanism is likely to be simpler and characteristic of other animals as well.

### Sunk Cost

The sunk cost effect occurs when one allows an amount of money, time, or other resources already invested in an activity to affect one's decision to invest more resources. For example, one may sit through a film that one does not like because to leave would be to waste one's investment of the price of the ticket. But there is no way to recoup that already expended cost of the ticket, and by continuing to sit through the film, one is spending additional resources and time that could be better spent in other activities. Similarly, although economists generally warn against it, one may choose to continue with a failing business because of the past investment one has made in it.

This phenomenon comes under the general rubric of prospect theory (Kahneman and Tversky 1979) which suggests that humans will take greater risks to avoid a loss than to obtain a gain. The question is to what extent does this behavior stem from the cultural tenet to avoid wasting resources and to complete what one has started. If one could show that animals, such as pigeons, show the same behavior, it would suggest that sunk cost is a general phenomenon that has basic behavioral origins.

In fact, evidence for sunk cost has been found in pigeons (Navarro and Fantino 2005; Pattison et al. 2012). For example, pigeons learn that pecking a green light requires 30 pecks, whereas pecking a red light requires only 10 pecks. They then learn that after pecking the green light a number of times (that varied from trial to trial), they would be able to choose to continue with the green light (to complete the 30 pecks) or switch to the red light for which 10 pecks were required. Results indicated that the pigeons often chose to return to the green light even when 20 more pecks are required. Thus, pigeons show a sunk cost effect that is very similar to that shown by humans. Why pigeons show the sunk cost effect is not clear. One can speculate that it arises from the fact that in nature switching to a different *patch* often involves uncertainty, some travel time, and possible danger. In any event, one can conclude that culture and language are not necessary components.

### When Less Is More

When humans are asked to judge the value of a set of objects of excellent quality, they often give it higher value than those same objects with the addition of some objects of lesser quality (Hsee 1998). It has been found when humans are asked to judge the value of sets of dishes or sets of baseball cards (Hsee 1998), and it also has been found when academics are asked to judge the quality of a curriculum vita (Hayes 1983). For example, a vita with three publications in excellent journals is judged better than one with the same three publications in excellent journals plus six more in lesser-quality journals. This bias is an example of the affect heuristic in which humans appear to judge the average quality of a set of objects to determine the value of the set rather than the total number of objects in the set. The phenomenon has become known as a less is more effect.

Recent evidence suggests that even pigeons are susceptible to this bias. For example, pigeons will work for dried peas and dried milo seeds, but when given a choice between the two, they prefer the peas. However, when they are given a choice between a pea and a pea together with a milo

seed, they prefer the pea alone (Zentall et al. 2013). Apparently, the pigeons, too, are averaging the high-quality pea with the lower-quality milo seed and value the pair less than the pea by itself. Similar results have been found with monkeys (Kralik et al. 2012) and dogs (Pattison and Zentall 2014). The basis of this bias may originate in the need to make rapid decisions, presumably because of intense competition from conspecifics and the possibility of predation, and they use this heuristic in the laboratory even when speed is not a factor. Once again, the fact that other animals show this sub-optimal choice indicates that the bias is probably not dependent on human cultural influence.

## Conclusions

The broad range of positive research findings that have come from investigating the cognitive abilities of animals suggests that many of the “special capacities” attributed to humans may be more quantitative than qualitative. In the case of many cognitive learning tasks, once we learn how to ask the question appropriately (i.e., in a way that is accommodating to the animal), we may often be surprised with the capacity of animals to use complex relations.

In evaluating the animal (and human) intelligence literature, we should be sensitive to both the overestimation of capacity (what appears to be higher level functioning in animals that can be accounted for more parsimoniously at a lower level; see Zentall 1993) and the underestimation of capacity (our bias to present animals with tasks convenient to our human sensory, response, and motivational systems). Underestimation can also come from the difficulty in providing animals with task instructions, an aspect of the assessment of intelligence that is often underappreciated (see Zentall 1997). The accurate assessment of animal intelligence will require vigilance, on the one hand, to evaluate cognitive functioning against simpler accounts and, on the other hand, to determine the conditions that will maximally elicit the animal’s cognitive capacity.

The study of human biases by examining animals for the presence of similar phenomena in

animals can also help us to determine if simpler mechanisms are involved. Thus, the study of animal intelligence not only can inform us of the cognitive abilities of animals but also can suggest the bases of certain human phenomena thought to have complex social origins.

## Intentionality

Juan-Carlos Gómez

School of Psychology and Neuroscience,  
University of St. Andrews, St. Andrews, UK

## Definitions

The term “intentionality” has two related but different meanings. One, normally associated with psychology, refers to the ability to act

purposefully or deliberately, guided by intentions in the sense of mental representations of goals. The second, associated with philosophy, refers to the property of mental states to be about an object or be directed to a content – we do not simply perceive or think: we see something, think about something, or desire something.

The psychological meaning is more restricted: it applies only to particular types of mental states with a goal or purpose. The philosophical sense includes the psychological one (all purposeful intentions are about something) but extends to all other mental states. For example, we may accidentally hear or see something. This is unintentional in the psychological sense, but intentional in the philosophical one, since our accidental perception has a content, is *about* something.

## Intentionality as Aboutness

The philosophical sense was proposed by the philosopher Franz Brentano to capture the fundamental property of mental phenomena that distinguishes them from physical phenomena. For Brentano, mental phenomena cannot exist on their own but are always “directed at” something and have a content different from themselves. This content needs not be a real object – it can be an imaginary or nonexistent one, like thinking of a unicorn or of an event that has not yet happened (e.g., an impending trip). The objects of mental states therefore may exist only “intentionally,” i.e., in the mind of the thinker (Crane 1998).

Dennett (1983) introduced this sense of the term to comparative psychologists and ethologists with a proposal to adopt the “intentional stance” in animal psychology, i.e., to describe animal behavior in mentalistic (intentional) terms: animals as agents that desire, believe, know things, etc.

He proposed a schema with different levels of potentially recursive intentionality to think about animal behavior. A zero-level intentionality account would correspond to reflex-like or conditioned reactions where animals have no anticipation or representation of the world but just act as some sort of automata responding to stimuli. For instance, to use Dennett’s own example about vervet monkeys’ alarm calls, at *zero-level*

intentionality, a monkey responding to the presence of a leopard with the leopard alarm call, or a monkey reacting to the call with the appropriate escape response, would be merely engaging in reflex reactions devoid of understanding or representation. With *level 1 intentionality*, monkeys would call because they *perceive* a predator and thereby give the alarm, maybe with the purpose (intentional in the psychological sense) that the other monkeys escape. With *level 2 intentionality*, monkeys would in addition represent others' knowledge or desires, for example, they could "intend" that the other monkeys "notice" the predator and run away. This level ascribes to animals a "theory of mind" ability – the ability to entertain mental states about mental states (see below). With *level 3* of intentionality, they would, for example, *intend* to make another animal *know* that they *want* them to go away or that they have *seen* a predator and so on. For some this latter level 3 would be the minimum required for communicative intentionality (see later).

Although Dennett's schema was proposed from the wider philosophical meaning of the term (intentionality as aboutness), it is frequently used by psychologists with the more specific meaning of intention as goal-directedness, especially in discussions of animal communication.

Dennett offered his "intentional stance" approach not as an "a priori" explanation of animal behavior but as a tool to help frame empirical questions, for example, designing experiments to probe at what level of intentionality vervet monkeys produce their alarm calls. Some expressed concern that such liberality in cognitive terminology may lead to unsubstantiated mentalistic claims about animal behavior if based on purely observational evidence, defending experimental evidence as the sole reliable empirical source to probe animal intentionality (Heyes and Dickinson 1990).

### Intentionality as Purpose

In psychology the more frequent sense of intentionality is as purpose, i.e., the ability to mentally represent goals and the means to achieve them through goal-directed, deliberate behaviors. In comparative psychology intentionality in this

sense has always been at the heart of disputes between reductionist, mechanistic stimulus-response models and cognitive interpretations of animal behavior based on teleological models of causation (Dickinson 2011).

Early comparative psychology (e.g., Romanes and his followers) was liberal in uncritically attributing to animals intentions and purposes among other mental states. However, the advent of behaviorism at the beginning of the twentieth century, both in its American (e.g., Thorndike, Watson) and Russian (Pavlov) strands, questioned the use of such mentalistic, folk-psychological notions in the scientific study of animals and even humans (Boakes 1984).

The behaviorist account was that purposeful behaviors could be explained as caused by acquired stimulus-response (S-R) associations. For example, a rat in a Skinner box pressing the lever could be folk-psychologically described as "acting with the intention to get food from the feeder." However, the behavioristic explanation is that rats are caused to press the lever by their past learned associations between the physiological state of hunger, objective discriminative stimuli, and the appearance of food. Rats press the lever not *in order to* get food but *because* they got food in the past. Operant conditioning works analogously to natural selection – through "selection by consequences," the former in the lifetime of individual organisms, the latter in phylogenetic time. In the same way that animal morphological features may appear to be designed with a purpose, when in fact they are the result of blind natural selection, acquired behaviors that appear to be purposeful may be the result of selection by contingencies of reinforcement (Skinner 1981).

The underlying epistemological concern is that purposeful or teleological explanations proceed from the future to the past, instead of explaining the future from past and current causes. This would be a logical impossibility, as the future has not yet occurred. Against this concern, one could argue that it is not the future itself that causes behavior but a representation of (possible) future events, i.e., a current state of the nervous system that is itself caused by past and current events.

Early challenges to behaviorism's dismissal of intentionality came from Gestalt psychologists studying animal problem solving (Köhler 1921). They proposed the notion of insight to describe the way in which chimpanzees solve problems. This notion assumes that behavior is intentional and goal-directed, as animals select and organize their responses to problem situations through an intention to reach the target which dominates the perceptual and behavioral field. Intentionality of action is a cornerstone of notions of insight and practical intelligence.

From within behaviorism itself, there were also attempts at accommodating notions of purposeful behavior. The most important was Tolman's "purposeful behaviorism," which was partly an attempt to reconcile behaviorism with aspects of Gestalt psychology (Tolman 1932). Tolman proposed that behavior should not be analyzed at the S-R level but at a more molar level, one where the key organizational component of behavior is the goal or purpose of the action, which controls the behaviors selected by organisms in different situations. His aim was to provide objective, scientific, non-mentalistic definitions of purpose and other cognitive notions. Tolman's approach has influenced modern behaviorist approaches in which notions of goal-directedness and intention are accepted and operationalized, but in the 1940s and 1950s, they were not the mainstream behaviorist approach to animal behavior.

## Intentionality and Goal-Directedness

With the advent of the cognitive revolution in psychology and related disciplines in the 1960s, notions of purpose and intentional action returned to the forefront in the study of human and animal behavior (Miller et al. 1960). In the 1940s–1950s, the new discipline of cybernetics (Wiener 1948/1961) had showed that notions of goal-directedness and purpose were necessary to explain the behavior of mechanical devices with negative feedback loops that allow for self-correction until a goal state is achieved (e.g., a self-guiding missile). It seemed unsustainable to keep avoiding in psychology notions that were

useful in explaining the behavior of mechanical devices. Cybernetics provided objective models of intentional action that could be applied to human and animal behavior. Stimuli not simply trigger responses but activate mechanisms controlled by feedback loops, one of whose key components is some internal instantiation of goal states and an ability to evaluate provisional outcomes against set goals and change behavior accordingly.

Animals started to be seen as "goal-seeking agents that acquire, store, retrieve and internally process information at many levels of cognitive complexity" (Menzel and Fischer 2011, p. 2). Accounts of natural and captive animal behavior started to use again notions of purpose, as part of a broader "intentional stance" (Dennett 1983; see above). There was, however, concern that the attribution of intentionality should not become an uncritical default assumption for animal behavior without appropriate experimental scrutiny. For example, Dickinson proposed that intentional goal-directedness exists only when behavior is controlled by "knowledge of the instrumental relation" between actions and their associated consequences, in contrast with mechanical stimulus-response associations that, once learned, are automatically triggered by the presence of stimuli (Dickinson 2011). He argued that goal-directed behavior in rats is empirically demonstrated by the finding that, after learning to press a lever to get food through ordinary operant conditioning, they become less likely to respond if an aversion to that type of food is separately established. When placed again in the original training room, rats do not automatically react to the stimuli by pressing the lever. Their knowledge of the instrumental relation between lever pressing and food delivery modulates their response in view of the now aversive value of the goal.

## Criteria of Intentional Action in Nonverbal Organisms

Defining intentionality as goal-directed behavior has the potential advantage of objectivity – it is possible to appeal to observable features of behavior and use mechanical devices as objective models of intentionality, which may in principle

be investigated independently of the question of consciousness (Burghardt 1991).

Like animal psychologists, developmental psychologists studying preverbal infants face a similar challenge in defining and identifying intentionality. Piaget (1936) made the ability to coordinate schemas of action in increasingly complex means-ends structures a pillar of infant sensorimotor intelligence during the first 2 years of life – from simply holding an action (grasping an object) until another act (pushing aside an obstacle) makes it viable to the innovative use of tools as intermediaries to reach goals. Piaget defined intentionality behaviorally as “the differentiation between means and ends,” but he also emphasized that cognitively this differentiation resulted in an “awareness of desire or the direction of actions, with this awareness itself being a function of the number of intermediary actions needed for the main act” (Piaget 1936).

Bruner (1973), building on cybernetics-inspired notions of goal-directedness, proposed a set of behavioral criteria to identify intentional action in preverbal infants. These included anticipation of outcomes, cessation of means deployment when the end state is achieved, and continuation with selection of alternative means when the goal is not achieved. Some of these criteria may themselves require further specification and operationalization. Developmental and comparative psychologists typically use variants of these criteria to identify intentional action in nonverbal organisms.

### Is Intentionality the Same as Goal-Directedness?

Some authors have proposed more nuanced distinctions. For example, McFarland (1989) distinguishes between goal-achieving, goal-seeking, and goal-directedness. Goal-achieving and goal-seeking systems behave in such a way that an end state is reached by virtue of the physical forces at work in a given system, but there is no representation of the goals. For example, a ball thrown spinning into a bowl will always reach the minimum down point, as if “seeking” it, but there is no representation of the end point guiding the ball, just an inevitable end outcome given the mechanics of the ball and the physical situation.

Genuine goal-directedness, for McFarland, requires an explicit representation of the goal, and when this representation is mental, then we have intentional behavior. McFarland warns that most instances of apparent goal-directed and intentional behavior in animals may in fact be explained as goal-achieving or goal-seeking and that this might be the case also for humans, even if through introspection we may believe ourselves that a given action is intentional.

For many a hallmark of intentionality is still the awareness and mental representation of the goal (and the means) that may precede and guide the execution of goal-directed actions. The intentionality displayed by living organisms may be different to mechanical goal-directedness. Intentionality with explicit representations of goals and means may allow for more flexible adaptive responses, as in the above example of the rats refraining from pressing the lever when they separately learn that the food is now aversive. However, defining what counts as explicit versus implicit representations of goals may prove to be challenging, as part of the more general problem of characterizing implicit vs. explicit knowledge (Gómez et al. 2017).

One advantage of intentionality is behavioral flexibility – the same goal can be pursued with alternative means adjusted to different circumstances. The particular means displayed by any given organism may depend upon their understanding of the causal structure of the situation (e.g., a chimpanzee or a corvid confronted with an out-of-reach reward may display tool use, whereas other animals may just try to find alternative routes to approach it). Definitions of intentionality tend to emphasize the representation and awareness of the goal; however, awareness and representation of the means and their causal relation to the goals are an equally important component. This might be a criterion to distinguish mere goal-directedness or goal-seeking from intentionality. The essence of intentionality as purpose lies in the representation and coordination of both means and ends.

### Planning

Mentally representing goals and means may allow to *think* about how to reach goals when they are

not immediately available and to keep them in mind while performing the indirect behaviors required to get them. Planning – thinking of means to a goal before being in a position to execute them – is a complex example of intentionality. It is contentious how much advanced planning animals are capable of and in how much detail they can represent goals and means before executing goal-directed actions.

In insight tasks it is frequently discussed to what extent the steps of a solution are planned in advance. For example, crows pulling a string to get food attached at its end may proceed through a loop of perceptual-motor feedback where the act of pulling is reinforced and maintained by the sight of the approaching reward. This perceptual-motor feedback explanation assumes goal-directedness but denies planning – a mental representation of the solution guiding the behavior of pulling – because crows without access to immediate visual feedback of the approaching reward stop pulling without realizing that perseverating will eventually get them the reward (Taylor et al. 2012).

Experiments on episodic memory and prospective planning show that apes may secure tools well in advance of being in the situation where they can use them (Osvath and Osvath 2008). For example, apes can take with them a tool that they will not be able to use to get food until much later and in a different room. They can even do this overnight, which suggests a robust ability to plan goal-directed actions in the future irrespective of their direct execution and without immediate direct feedback.

There is probably no sharp divide between pure goal-directedness in sensorimotor systems (which, one could argue, may not require explicitly represented intentions to guide behavior) and pure offline representational planning separated from active implementation but a continuum of possibilities where both may be combined to different degrees.

## Intentions About Intentions: Theory of Mind

Intentionality, both in the philosophical and psychological senses, is related to the problem of

whether animals are capable of attributing mental states to others. In Dennett's schema (1983), this involves having intentions about intentions – second-order intentionality. Intentionality as purpose featured in Premack and Woodruff's (1978) pioneering paper that introduced the notion of theory of mind. They asked if a chimpanzee watching a human stretching his arms toward a bunch of inaccessible bananas would just code the physical characteristics of the movements or also the underlying intention giving sense to the behavior – the goal of obtaining the bananas. They concluded that chimpanzees attribute intentions because, after watching videos of a human trying to solve problems like this, their subject was able to select photographs depicting correct solutions (e.g., the human stepping onto a chair).

Apes understand goal-directed action in other agents, visually anticipating where agents will search for their goals (Kano and Call 2014). Whether this is done through the attribution of intentions as unobservable mental states or through some alternative mechanism relying on observable properties of behavior is subject to debate as part of the more general problem of theory of mind in nonhumans.

One alternative approach to animal mentalism, building upon Brentano's notion of intentionality as aboutness, proposes that animals code intentionality through the perception and representation of "directedness" as a Gestalt quality of behavior, not as a derived property of inferred mental states. For example, gaze following may not require attributing subjective experiences of seeing or attending but perceiving the behavior of looking as being *about* or *directed at* particular objects. Such coded intentional relations may in turn be kept in memory as information concerning the "intentional availability" of objects to agents. Evolution may have selected adaptations to behaviorally express and detect relations of intentionality between agents and objects (including other agents). In this way organisms may adapt to a variety of intentional states based on perceived properties of aboutness, rather than inferred unobservable representations (Gómez 2008).

## Communicative Intentionality

Animal communication can be studied without any reference to intentionality, and indeed some scientists prefer an approach to communication that is agnostic about animal intentions. Communicative signals can be described and classified and their functions analyzed in terms of antecedents, consequences, context, and functions without addressing the problem of intentionality (Slater 1983).

However, many comparative and evolutionary psychologists are interested in whether animals can produce communicative signals intentionally. The debate about intentional communication in animals is more complex than the debate about individual intentionality because it has been proposed that communicative intentions may be different to individual intentions. The issue is complicated by disparate definitions and (often implicit) assumptions and criteria across different authors and approaches, which in part reflects wider-spread unresolved debates in psychology and cognitive science about the nature of intentional communication in humans.

There is extensive evidence that many animal species produce signals with the goal of affecting others' behaviour (level 1 intentionality in Dennett's intentionality schema; see above), but there is disagreement about whether they understand how signals work by affecting others' mental states. Accounts of intentional communication in humans usually consider that, to be communicative, the intention behind a signal must refer to the mental states of the receiver, which in Dennett's terms would imply higher orders of intentionality.

### Communicative Intent and the Notion of Ostension

In humans communicative intentions have been proposed to be special, more complex than ordinary intentions. An influential line of analysis (Grice 1957; Sperber and Wilson 1986) proposes that in communication humans combine two types of intentions – *informative* (e.g., conveying the information that I want water) and *communicative* or *ostensive* (conveying the information that

I want to convey the information that I want water). Sometimes we just act with an informative intention (e.g., by covertly pretending that I am trying to drink from an empty glass I can try to make my host understand that I want water, without asking for it openly). However, when we openly ask for water, we *want* not only that our host *understands* that we *want* water but also that we *want* her to *understand* that we *want* water, which adds up to at least five orders of intentionality, with an ostensive “loop” of mutually embedded intentions that appears to be cognitively very demanding.

There are two important things in relation to this analysis. First, this implied cognitive complexity is counterintuitive, in that it does not appear to correspond to our subjective experience in everyday communication. Second, ostensive communication does not require language because we could simply show our host the empty glass of water and smile while looking at her to convey our message. It is therefore in principle possible that nonlinguistic organisms engage in ostensive communication.

Indeed human infants are credited with ostensive-like communication from as early as 9 months of age when they start addressing pointing gestures to others to request and show things of interest. Showing gestures, sometimes dubbed “protodeclaratives,” have been hailed as an important proof of communicative intent, because the infants seem to try to influence the mental states of others in an open, intentional way. In contrast, apes mainly engage in “imperative” gesturing to request actions from others, but rarely, if at all, produce declarative gestures. This could indicate that they only act pursuing individual goals of the type “give me X” but without ostensive communication that would require more complex mentalistic intentionality (Scott-Phillips 2015).

However, although apes' ultimate goal might be affecting others' behavior, they may still show mentalistic intentionality, because in their requests they display joint attention behaviors. For example, they address their gestures to the recipients seeking eye contact with them (an acknowledged marker of ostension in

humans) and even call the attention of recipients that are distracted (Leavens and Hopkins 1998).

This may indicate that, within their imperative motives, apes may use forms of ostensive communication. However, these may not require recursive, mutually embedded intentionality, as ostensive functions can be achieved through joint attentional behaviors, such as eye contact, where any recursive intentionality would remain implicit. Ostension without recursive intentions may help understand how humans engage in ostensive communication without explicitly going through the steps suggested by Gricean analyses (Gómez 1996).

An alternative approach is to avoid the Gricean intentionality issue in animal research and concentrate on simple goal-directed intentionality avoiding the notion of ostensive intentions, so difficult to test objectively. The challenge of a fully empirical approach is to find objective markers of goal-directed communication. Building on the efforts of students of prelinguistic communication in human infants, several authors have proposed behavioral criteria of intentional communication, such as persistence until reaching the goal, orientation to the receiver, or variation in means displayed as a function of the outcome (Townsend et al. 2017). However, the fact that criteria like these may be met by very distantly related species, such as fish (Vail et al. 2013), creates the doubt of whether existing objective criteria are fine-grained enough to capture any peculiarities of communicative intentionality. In addition, any attempt at defining in empirical detail the criterion of “orientation to the receiver” may need to eventually address the problem of ostensive intentions.

### Shared Intentionality

Closely related to the problem of communicative intentionality is the issue of shared intentionality. It has been proposed that a distinctive human ability is to form and pursue joint or shared intentions in cooperative contexts, when we need to engage in complementary activities without which a goal would be unattainable (e.g., moving together a piece of furniture). This “we” intentionality allows the coordination of collective action

and is assumed to require not only an understanding of each other’s intentions and knowledge but to overtly share this. Tomasello and Carpenter (2007) suggest that this might be a distinctive human ability, with apes remaining at a level of individual intentionality, pursuing individual goals, where they can attribute intentions to others, but not “share” them with others to coordinate their actions and achieve goals jointly. For example, although in competitive contexts chimpanzees interpret *reaching to* a box as a signal of their rival’s intention to get food there, they find it difficult to interpret *pointing to* the box as a cooperative signal intended to tell them where the food is (Hare and Tomasello 2004). Shared intentionality would require special forms of cognition and cooperative motives and would be at the root of human culture.

Other authors argue that, although humans indeed excel at shared intentionality, this is already present in nonhuman primates, because they are capable of engaging in cooperative activities in the wild (e.g., hunting) and in captivity (solving problems that require joint coordinated action). The debate is about whether it is possible to explain this cooperative action as a result of coordinating individual intentions without “sharing” them, which poses a difficult problem of definition of what should count as “shared” versus “coordinated.” It has been suggested that the evolutionary roots of shared intentionality may be deeper and could be found in the elaborate social play displayed by mammals, especially primates (Heesen et al. 2017).

### Conclusion

Notions of intentionality – both in the sense of aboutness and purpose – have been applied or rejected in the study of animal behavior in different ways and at different times. They have always been at the center of debates between behaviorist and cognitive approaches to animal behavior. In some formulations (intentionality as individual goal-directedness), they are currently accepted as relevant and empirically grounded even by modern learning theorists and used in the study of a

variety of aspects of animal behavior and cognition, although problems of definition and scope still persist. Notions of communicative intentionality remain more controversial and subject to polarized debate, due to lack of conceptual agreement and the difficulty of finding reliable behavioral indicators of the cognitive and motivational components of communicative intent. Intentionality touches upon some central epistemological problems about the nature of explanation in animal behavior and the methodological challenge of going beyond observable behavior and finding objective behavioral criteria of cognitive processes.

## Interbirth Interval

D. Susie Lee  
Department of Anthropology, New York  
University, New York, NY, USA

### Definition

An interbirth interval (IBI) is the period in between two consecutive births. The interval often takes into account only viable births, ignoring miscarriages, still births, or premature deaths. IBI is only meaningful for iteroparous species, which reproduce in multiple bouts over the course of a reproductive lifespan. Most available data on IBI tend to focus on the clade Placentalia and

particularly on large-bodied taxa with low reproductive output per bout, such as carnivores, elephants, primates, ungulates, and whales. In humans, where conception date can often be identified, IBI may be replaced by “inter-pregnancy interval,” defined as the period in between delivery of a live-born child and the estimated conception of the next pregnancy. In egg-laying taxa, such as amphibians or birds, the concept of IBI may be expanded to the time interval between consecutive clutches or the number of clutches produced per breeding season.

### IBI in Life history theory

IBI is a key life history variable used to characterize the pace of reproduction of a species. Across mammals, IBI is positively correlated with weaning age, age at sexual maturity, and gestation length (marsupials only), independently of body size variation (Promislow and Harvey 1990). Within species, the IBI is a major determinant of female reproductive success, together with the total reproductive lifespan, and offspring mortality (Clutton-Brock 1988). Lifetime reproductive success would be maximized by frequent reproduction, i.e., shorter IBIs, only if reproductive lifespan and offspring mortality exert their effects on reproductive success independently of the IBI. However, too short an IBI is not optimal because IBI co-varies in particular with offspring quality, such as survival, birth weight, small for gestational age, or reproductive success later in life. For example, in humans, the risk of adverse birth outcomes increases as inter-pregnancy intervals decrease (Blurton Jones 1986; Conde-Agudelo et al. 2006; Wendt et al. 2012). Similarly, in Great Tits, the offspring of parents whose following clutches had been experimentally removed were tended for a longer period and enjoyed higher survival rate in their first year of breeding (Verhulst et al. 1997). The negative correlation between IBI and offspring quality has been explained using life history theory, which posits that investment in offspring number utilizes finite resources that would be otherwise available for

investment in offspring quality (Stearns 1989). Following this view of life history trade-offs, a shorter IBI means insufficient restoration of resources depleted from investment in the previous reproductive event, consequently limiting the resources available for current reproduction. As a result, short IBIs would undermine the quality of current offspring, in the form of negative birth outcomes or lower reproductive success for the current offspring later in life.

### IBI as a proxy of parental investment

Due to the trade-off relationship between IBI and offspring quality, the IBI is seen as an index of parental investment, which is any investment in one offspring at the cost of a parent's ability to invest in future offspring. It is adaptive for a parent to keep an IBI short so that it does not compromise the parent's chance of producing future offspring. It is therefore likely that mechanisms for regulating IBI have evolved to maximize parental fitness depending on the context. For example, a study on a British human birth cohort has shown that IBIs are shorter when previous offspring are in severe but not fatal medical condition. This finding suggests that parental investment would be reduced for offspring displaying low expected fitness. Increased resource availability is another context in which IBIs can become shorter. Compared to great apes (>5 years), human IBI lengths in natural fertility populations (in the absence of controlled fertility) are in general shorter in their median length (3.5–4 years). The shortening of human IBI lengths may suggest that the costs involved in short IBI – notably, the deprivation of maternal resources and its consequence for the following infant – have been effectively alleviated through co-evolved strategies, such as cooperative breeding and earlier food supplementation for weaning.

### IBI in mammals

The mammalian IBI is comprised of three main phases: (i) postpartum anovulation (PPA);

(ii) cycling; and (iii) gestation. Variation in the length of gestation is small relative to the length of the first 2 periods that constitute time to maternal re-conception. In particular, PPA has gained most attention for its contribution to the variation of IBI. In most mammals, suckling during lactation and the presence of and physical interaction with offspring suppress maternal reproductive function. Thus, some maternal behavior (e.g., rejection of an offspring's nipple contact attempt) and some offspring behavior (e.g., tantrums, begging) may influence the duration of PPA. Food resources and energy balance might have particularly strong influences on the lengths of both PPA and cycling. In seasonally breeding mammals, the length of cycling may be additionally influenced by environmental cues linked to seasonality, such as photoperiod, precipitation, and temperature. For example, among rodents, there is a general trend for an increased length of breeding season with increased interval between successive litters.

Texas Health Science Center at Houston,  
Houston, TX, USA

Investigations of animal memory have traditionally been studied in terms of how long animals can remember single items, often in delayed matching-to-sample tasks. Results from some delayed matching-to-sample tasks can be seen in Fig. 1a for capuchin monkeys (filled squares), macaque monkeys (filled circles, diamonds), and pigeons (unfilled circles). These studies all used just two stimuli (See Wright, 2007 for references of these studies and further discussion). The sample presented on each trial was one of the two stimuli, followed by a delay and then a choice between these two stimuli for which stimulus matched the sample. With no delay (0s), performance accuracy was more than 80% correct. But performance rapidly declined, reaching 50% correct (chance performance) in 1 min or less. At issue is what do such results tell us about animal memory? Such results are unlikely to convey limits of the animal's memory because the animals would not be able to survive (e.g., remember food source locations, nesting sites, mates, filial relationships, dominant individuals, and predator locations). But for one study included in Fig. 1a (filled circles), the 2 stimuli were increased to 100 stimuli and then further increased to all novel stimuli (Fig. 1b). These stimulus increases resulted in progressive and dramatic increases in memory performance (Overman and Doty 1980). Indeed, even after a 24-h delay, performance was better than after 30s in the two-stimulus condition!

Consider what an animal faces when making a choice in the two-stimulus condition. The animal is presented with the same two stimuli on every trial and must decide which stimulus matches the sample stimulus. Even after a brief delay,

**Interference, Fig. 1 (a)**

Four single-item memory functions from different laboratories using only two stimuli in delayed matching-to-sample experiments: macaque monkeys (filled circles and filled triangles), capuchin monkeys (filled squares), and pigeons (unfilled circles). (b) Three delay functions with rhesus monkeys (Overman and Doty 1980). The two-stimulus function is the rescaled filled circle function from (a) above. In the 100-stimulus condition, repetitions of the stimuli were separated by many trials. In the novel stimuli condition, all stimuli were novel and trial-unique. Dotted lines represent chance performance

confusion can occur as to which trial the test stimulus had been seen and processed. This issue of proactive interference adversely affecting later memory performance can be present in virtually any memory task as Keppel and Underwood showed in 1962 for the buildup of proactive interference (and increase in errors) as humans experienced an accumulation of stimulus repetitions over the testing session.

### Proactive Interference in Pigeon and Monkey Same/Different Tasks

#### Pigeons: Time-Based Proactive Interference

Proactive interference similar to that which occurs in delayed matching-to-sample tasks also occurs in same/different tasks. In same/different tasks, one (sample) stimulus is presented (to be remembered), and after a delay, a second (test) stimulus

is presented in a location below the previous sample stimulus (Fig. 2a). If the test stimulus matches the sample stimulus, then a response to the test stimulus is correct. If the test stimulus does not match the sample stimulus, then a response to the white rectangle to the right of the test stimulus is correct. In same/different tasks, proactive interference (PI) occurs when a previously seen sample is re-presented as a test picture on later *different* trial. Having seen that test picture before, possibly as a sample stimulus in the immediately previous trial, tends to create confusion and increases the likelihood that a *same* response (incorrect response) will be made (Fig. 2a). Since stimulus repetitions in general produce cumulative proactive interference, to evaluate PI, the vast majority of trials in a session would need to involve trial-unique stimuli (i.e., without proactive interference). With such a background of low or no-PI, only then can occasional test trials of proactive interference be

**Interference, Fig. 2** (a) Example of two trials from proactive interference tests with pigeons where the interfering stimulus was presented on the preceding trial ( $n-1$ ) and repeated as the test stimulus on trial  $n$  with 10-s delay between offset of sample stimulus and onset of test stimulus. (b) Signal detection theory model of elapsed time: log

time to the sample on the current (test) trial ( $\log T_C$ ) and log time to the interfering sample ( $\log T_I$ ). (c) Percentage correct performance for 1- and 10-s delays, with model fits (1-sigma bands) based on the ratio of log times ( $T_C/T_I$ ) – see Wright et al. (2012) for further details

inserted within a session to test how far back in time PI can affect memory accuracy.

One such PI test was conducted with four pigeons (*Columba livia*) for interfering stimuli that were presented 1–16 trials previous to the test (Wright et al. 2012). A large stimulus set of 1024 images (pictures of objects, natural scenes, animals, etc.) was used so that stimuli would be trial-unique and not repeated for more than 2 weeks of testing. PI was tested by placing potentially interfering stimuli either 1, 2, 4, 8, and 16 trials prior to test trials. Pigeons pecked the sample stimulus 20 times, followed by a delay (1 s or 10 s, in a block design), a test stimulus and white rectangle, a choice response, and a 15-s intertrial interval. Each daily session consisted of 64 trials with 5 interference tests (1 test each at the 1-, 2-, 4-, 8-, and 16-trial separations). Trials other than those of the interference tests (*no-PI*, or baseline, trials) contained randomly selected (without

replacement) pictures from the 1,024 picture set. There were 32 *same* and 32 *different* trials per session, 24 sessions per block, and 4 blocks alternating between 1-s and 10-s delays.

Even with the shorter 1-s delay, there was considerable PI, and this PI dissipated as a function of increased trial separation (Fig. 2c). With the longer 10-s delay, there was a considerably larger 47% PI effect with the interfering stimulus in the preceding trial which dissipated with increasing trial separation, but there was still a residual interference effect of 11% for stimuli presented 16 trials prior (more than 6.5 min prior), considerably greater than that with the 1-s delay.

Greater interference at the longer 10-s delay than at the shorter 1-s delay is counterintuitive. Interfering stimuli encountered more distantly in the past (144 s at  $n-16$  for 10 s vs. 1 s) should, according to models of decay or limited capacity,

translate to more forgetting and therefore less interference. But just the opposite occurred. This counterintuitive finding was shown to obey a Weber-Fechner time ratio of time discriminations (Fig. 2b) from the test to the current-trial sample stimulus divided by time to the interfering stimulus (see Wright et al. 2012). Longer testing delays allow for greater opportunities for noise to come between the current sample and test and increase chances that the interfering stimulus will adversely affect the correct *different* response and enhance the chances of making an incorrect *same* response. This model based on the Weber-Fechner time ratio of time discriminations was fit simultaneously to both PI functions using the same parameters (bias and maximum accuracy) accounting for 95% of the variance, including the no-PI condition (Fig. 2c).

#### Monkeys: Event-Based Proactive Interference

Three rhesus monkeys (*Macaca mulatta*) were tested in same/different memory tasks for proactive interference (PI) from prior trials (Devkar and Wright 2016). Most of the conditions including trial-unique pictures selected from the same 1024 picture set without replacement on baseline trials; interference tests separated by 1, 2, 4, 8, or 16 trials prior; 15-s intertrial intervals; numbers of trials per sessions; sessions per block; and repetitions of blocks were the same for monkeys as they were for pigeons (described above). One difference was that monkeys were tested with three delays (1-s, 10-s, and 20-s delays). The 20-s delay was used to explore better the limits on time-based proactive interference. Nevertheless, there was no evidence of time-based proactive interference in monkeys (i.e., no statistical significant differences or interactions for the three PI functions of Fig. 3a).

As a follow-up test to further explore the possibility of any time-based proactive interference in monkeys, a shorter intertrial interval of 5 s was tested to increase interactions among stimuli from different trials and possibly enhance any time-based proactive interference. In this study, the 20-s delay was used which also should enhance any time-based proactive interference across trials. The longer 15-s intertrial interval was retested for comparison and alternating block testing

design. Decreasing the intertrial interval by this amount (66.6%) decreased time to the interfering stimulus by 10s per trial (i.e., 160 s for 16 trials), and any time-based proactive interference like that shown for pigeons should be increased proportionately.

Even with these shorter 5-s intertrial intervals and longer 20-s delays, there were no statistical differences between the PI functions for 5-s versus 15-s ITIs (Fig. 3b). Despite a lack of any time-based PI, all PI functions showed pronounced PI effects. Moreover, these PI functions covered a very large performance range, as much as a 50% accuracy range (e.g., 40–90% accuracy). Such large proactive interference effects along with a total lack of time-based proactive interference converge on the conclusion that these primates' proactive interference is *event* based. Event-based versus time-based PI conjures up well-known processing distinctions of remember versus know judgments, explicit versus implicit memory, and episodic versus familiarity memory.

#### Interference in List Memory Tasks

List memory tasks are closely related to same/different tasks which should make them susceptible to the same buildup of proactive interference when small sets of testing stimuli are used and other manipulations to produce proactive interference functions. Many animals trained in list memory tasks are first trained in same/different tasks, followed by gradually expanding the number of sample stimuli. List items are presented in the sample location (e.g., 1-s presentations and 1-s between items), followed by a delay, and then a test item appearing below the sample/list location. A response to the test item is correct when it matches one of the list items; a response to the white rectangle is correct when the test item does not match any list item.

In one study, monkeys and humans were tested for proactive interference with three-item lists (Fig. 4). Tests with a large set of 211-item picture set resulted in high accuracies of 93% and 96% correct for monkeys and humans, respectively. But when they were tested with a small six-item

**Interference,**

**Fig. 3** Mean performance for three monkeys with five different separations between an interfering stimulus and a test stimulus compared to no-interference (no-PI) baseline trials. **(a)** Three delays, 1-s, 10-s, and 20-s delays, with 15-s intertrial intervals. **(b)** 5-s and 15-s intertrial intervals with 20-s delays

picture set, accuracy fell to 70% and 89% correct for monkeys and humans, respectively (Sands and Wright 1980). In a related study, monkeys were tested with 4-item lists selected from a 420-item picture to be trial-unique each session. Over 3 months of testing, their overall accuracy of 75% correct declined to 60% correct. This gradual decline in accuracy was similar to that shown by Keppel and Underwood (1962) but over a longer time scale; novel stimuli tests resulted in an accuracy increase to 82% correct (Jitsumori et al. 1988).

Another study showed buildup and release from proactive interference by testing monkeys with four-item lists composed of examples from one of two categories (flower or primate face pictures). Over 40 trials of testing with one of the categories, accuracy dropped from 86% to

71% but returned to 86% when the switch to the other category was made and then dropped again over the next 40 trials with that category. This is an example of category-specific proactive interference, resulting in what has been termed “release from proactive interference” upon the category switch (Jitsumori et al. 1989).

PI function tests can be conducted with list memory tasks much like with the same/different task by test items that match a list item from a previous trial but not a list item from the current trial. Such PI tests were conducted with a rhesus monkey well trained in a ten-item list memory task. On occasional interference trials, interfering stimuli were placed one, two, three, four, five, or six trials prior to the test (Fig. 5). When the interfering items were in the immediately preceding trial, performance was 64% (with

50% being chance performance). As trial separation grew (to as many as 60 items prior), performance increased to 83% but was still less than the no-PI baseline performance of 93% correct (Wright et al. 1986). These findings show that

proactive interference can extend to as much as 60 items prior.

In conclusion, proactive interference is endemic to virtually all experimental studies of memory where stimuli and events are repeated. For some primates, certainly rhesus monkeys (and possibly humans), proactive interference is event based and varies inversely with the number of intervening events. For some bird/avian species, certainly pigeons, proactive interference is time based and varies inversely with the passage of time since the interfering event and directly with delay to the processing of the test stimulus (as ratio of log time). Of course, time is the interval between events, and events have to be distinctive to be remembered. Therefore, avian (pigeon) time-based proactive interference must at some level be event based as well. But as shown with primates (rhesus monkeys), proactive interference can be event based, exclusive of time-based proactive interference.

Because proactive interference is such an important component of learning and memory, it will be of considerable importance to determine the generality of the division of time-based proactive interference for avians versus event-based proactive interference for primates as described here. For example, an avian species with outstanding memory for events like the Clark's nutcracker (a corvid species) might provide a good test of event-based proactive interference because these

**Interference, Fig. 4** Repeated-item interference of a rhesus monkey's three-item list memory results with memory items selected from a low interference condition (low-PI) using a set size of 211 distinctly different items compared to high proactive interference condition (high-PI) with items selected from a small six-item set. Serial position 1 was the first list item. Unfilled symbols (diff) show performance on trials (*different*) where the test did not match any list item. The dotted line represents chance performance

**Interference, Fig. 5** Interference tests of a rhesus monkey's ten-item list memory performance as a function of the number of items occurring between a test item on a *different* trial and its previous presentation. The no-PI condition is a no-interference condition. The dotted line represents chance performance

birds depend on remembering the many locations (Where) of pine seed caches (What), which change yearly (When), and are recovered in the dead of winter when the forest is covered with snow. Perhaps the critical component for pure event-based proactive interference will turn out to be well-developed episodic or episodic-like memory (What, Where, and When).

(Note: there are retroactive as well as proactive effects among the items that make up lists, particularly auditory lists, but discussion of those within-list effects can be found in Wright (1999) and the *Encyclopedia* entry ► “List Memory Effects (Primacy and Recency).”

## Synonyms

Junk DNA; Spacer DNA

## Definition

“Stretch of DNA sequence located between the two successive genes.”

## Introduction

The human genome is an enormous, cryptic store of information with approximately three billion bases that encode, either directly or

indirectly, the instructions for synthesizing nearly all the molecules essential for the formation and function of each human cell, tissue, and organ. The genome of most of the eukaryotes comprises several protein-coding genes, nonprotein-coding genes, and transcription regulatory elements such as enhancers, suppressors, promoters, etc. In addition, there are sequences that are responsible for regulation of chromosomal structure and dynamics (Dunham et al. 2012). However, all these regions contribute to a very little fraction of whole genome and essentiality of much of genomic regions is yet to be defined. To understand the term “intergenic,” first, one must have knowledge of genes and the extent of genic region in the genome. To define the structure of **gene** precisely is very difficult; however, it can be defined as the entire DNA sequence including regulatory regions that can synthesize a functional protein or RNA molecule. **Intergenic regions**, also known as **spacer DNA** or sometimes **junk DNA**, are the long stretch of DNA sequences located between protein-coding regions of two successive genes (Shabalina et al. 2001). However, this definition is incomplete because there are many genes including genes encoding the t-RNA and r-RNA that are nonprotein coding and therefore, according to this definition can be considered as intergenic.

### Genic Versus Intergenic Region

In general, eukaryotic genes consist of multiple protein-coding regions, the exons, separated by non-coding regions, the introns, and 5' and 3' untranslated regions. In addition, they also include the regulatory regions such as promoters, enhancers, etc. The introns are stretch of noncoding DNA sequence between two successive exons. On the other hand, the genome of prokaryotes lacks introns in their genes. The untranslated regions of a gene are also noncoding but play essential role in regulating the stability and localization of transcripts. In contrast, intergenic regions do not encode protein and are poorly conserved in the genome. The length of intergenic regions varies in eukaryotic and prokaryotic genomes. For example, eukaryotic

genes are usually separated from each other by long stretch of noncoding DNA sequences, i.e., intergenic sequences, while intergenic regions of bacterial and yeast genomes and mitochondrial genome are comparatively very short or completely absent (Wolstenholme 1992). These regions are poorly defined and might have regulatory elements such as binding sites for transcriptions factors, enhancer, promoters, operators, etc. Intergenic regions differ from intragenic non-coding regions because introns are comparatively shorter in length and are highly conserved at their ends.

### Genome Architecture and Intergenic Region

Intergenic regions are very abundant and cover more than half of the entire genome in many eukaryotes. For example, in human, approximately 1% of the entire genome is comprised of the protein-coding exons and the remaining 99% of the genome are covered by introns (24%) and intergenic DNA (75%) (Venter et al. 2001). Of the intergenic DNA, nearly 44% is derived from transposable elements including long interspersed nuclear elements (LINEs), short interspersed nuclear elements (SINEs), long terminal repeats (LTRs), and cut-and-paste type elements (Fig. 1). LINEs are ~6 kb long repeat sequences that are present in hundreds-thousands in numbers either in transpositionally active (e.g., *L1* elements) or inactive form (e.g., *L2* and *L3* elements). In contrary, SINEs are 100–400 bp long repeat sequences and the second most abundant transposable elements in human genome. Most of the SINEs are transpositionally inactive (*MIR*, *MIR3*), except *Alu* elements which are the only active SINEs. LTRs are hundreds of thousands of identical or nearly identical DNA sequences of approximately 300 bp that are flanked at opposite ends of an integrated retrovirus or a retrovirus-like element. These transposable elements are repetitive sequences that are interspersed throughout the genome. Nearly 70% of entire human genome is comprised of repetitive and repetitive-derived DNA elements such as microsatellites and minisatellites which are dispersed

**Intergenic, Fig. 1** Diagrammatic presentation of components of a typical eukaryotic genic and intergenic region

in the intergenic regions also (Snustad and Simmons 2012).

Recent studies have shown that approximately 60–70% of the entire human genome is transcribed as either processed or primary transcripts (Djebali et al. 2012); however, only 2% of all transcriptional output encodes the proteins (Mattick 2001). The remaining 98% transcriptional products are nonprotein coding and include housekeeping noncoding RNA (r-RNA, t-RNA, and small nucleolar RNA (snoRNAs)), introns, plentitude of antisense transcripts, intergenic transcripts, and a large number of predicted transcriptional units (Mattick 2001). These noncoding RNAs can be categorized into small noncoding RNA, including microRNAs (miRNA) and small interfering RNAs (siRNA, etc.), and long intronic noncoding RNA and long intergenic noncoding RNA (lincRNA) that are dispersed throughout the genome. Both miRNA (or small temporal RNA) and siRNA are about 21–25-nucleotide long RNA molecules that are derived from the processing of approximately 70-nucleotide long double-stranded precursor hairpins by Dicer ribonuclease III. The genes encoding these small regulatory RNAs are dispersed throughout the intergenic and intragenic regions and occasionally in exons. Long intergenic noncoding RNAs (lincRNAs), also known as **dark matter** are a subset of long noncoding RNA that is transcribed by RNA polymerase II from the DNA sequences

between two successive genes. LincRNA undergoes processing by both 5' capping and 3' poly (A) additions and spliced (usually with alternative isoforms, but with fewer exons than coding mRNAs) and have an average length of 1 kb. In human genome, more than 8000 putative lincRNA transcripts have been identified so far; however, the number may be even more. These lincRNAs show a similar expression level and expression pattern to those of protein-coding genes, although they lack the protein-coding capacity. Additionally, these transcripts show significant evolutionary conservation compared to neutral sequences (Cabali et al. 2011). Moreover, these RNAs may also bind with chromatin regulatory proteins. Unlike to eukaryotic genome, prokaryotic genomes are much shorter and lack the intronic regions in their genes. Most of the regions of prokaryotic genomes are transcribed and translated to protein products; however, they do possess intergenic DNA sequences that transcribe noncoding RNAs, untranslated regulatory regions, and repetitive elements (Sorek and Cossart 2010).

## Functions of Intergenic Regions

Since intergenic regions are noncoding, they were often believed as **junk DNA** suggesting that they had no defined function in the organism. However, several studies in last three

decades have shown that these regions do encompass functionally essential regulatory elements such as enhancers and suppressors. Approximately, 99% of human and mice protein-coding genes have conserved sequence homology, suggesting that variations in the phenotypes of both the species are possibly due to differences in the nonprotein-coding sequences. In addition, the genome of higher organisms such as mammals is comparatively much bigger than the lower organism, e.g., *Caenorhabditis elegans*. However, numbers of proteins in mammals are only two- to threefold higher than in simple nematode *C. elegans* (Venter et al. 2001). Further, along with increase in the complexity of organism, there is a concomitant increase in the noncoding intergenic and intronic sequences (Mattick 2001). This suggests that intergenic regions of mammals are at least as functionally important as their genes, because the intergenic regions might hold the key to the complexity of mammals (Shabalina et al. 2001). Emerging evidences from several recent studies demonstrated that lincRNAs are implicated in various biological processes including cell-cycle regulation, immune surveillance, embryonic stem cell pluripotency, embryonic development, etc. For example, lincRNA-ST8SIA3 or lincRNA-RoR (regulator of reprogramming) modulate the cellular reprogramming and helps in the establishment and maintenance of pluripotency. However, exact molecular mechanism of lincRNA-RoR functioning is not known till date (Loewer et al. 2010). LincRNAs, for example, HOTAIR, which is highly abundant in breast cancer, may also regulate the cancer metastasis by targeting the chromatin-remodeling complex PRC2 (polycomb repressive complex 2) which eventually alters the H3K27 methylation and gene expression (Gupta et al. 2009). Studies in zebra fish have shown that two highly conserved lincRNA, i.e., linc-oip5 (cyrano) and linc-birc6 (megamind), play important role in brain morphogenesis and eye development, and these functions are retained in their mammalian orthologues (Ulitsky et al. 2011). These regions also regulate the endocrine differentiation of pancreatic tissues by acting as a transcriptional

enhancer and as a polycomb response element. In addition, intergenic spacer regions are useful in distinguishing the pathogenic and nonpathogenic strains of bacteria, fungus, and other organisms (Tokajian et al. 2016). Synthetic intergenic regions can also be used to attenuate the pathological activity of certain virus, e.g., hemorrhagic fever arenaviruses (HFAs), and thus might be helpful in preventing the high rate of morbidity and mortality across the world (Iwasaki et al. 2016). In plants, functions of lincRNA are relatively less studied; however, large-scale RNAseq and tiling microarray studies have revealed the presence of many lincRNA in the plants also. These lincRNAs regulate the gene expression by recruiting proteins regulating the chromosome modification, alternative splicing by binding and sequestering the proteins required for alternative splicing, and inhibiting the interaction between miRNA and their targets mRNA (Yamada 2017). Roles of miRNA and siRNA are well defined in the regulation of various morphological events including embryonic development. These small regulatory RNA bind to their target mRNA and regulate the expression of protein-coding genes in plants and animals.

## Conclusion

Studies in last few years have shown that lincRNA are not “junk” as described earlier and may have certain role in biological processes; however, our knowledge about the exact biological functions of these transcripts is limited and very few such transcripts have been defined, yet. Increasing knowledge about the role of lincRNA may be useful in developing diagnostic markers and treatment of several pathological conditions. Further studies may explore many more of these transcripts and would be helpful to solve the puzzle of huge volume of nonprotein-coding portions of the genome.

## Internal Clocks

Jennifer Swann and Emily Hall  
Department of Biological Sciences, Lehigh University, Bethlehem, PA, USA

## Definitions

Internal, biological clocks can be found in all organisms and regulate a variety of functions, including: learning and memory, reproduction, growth, and aging. Biological clocks, like our mechanical versions, are valuable because they synchronize the timing of events, coordinating

internal events with each other, and with the external environment.

Biological clocks can be classified in a number of ways. For example, clocks can be classified according to their mechanism into hourglass or interval timers and oscillatory clocks. Hourglass clocks, or “countdown” clocks, determine intervals and are found in processes that describe development, aging, and learning. Oscillatory clocks keep time, spontaneously regenerating with a fixed period and are found in processes that coordinate internal processes with naturally occurring cycles in the environment such as reproduction and feeding. Clocks can also be characterized by their period length. Those with periods less than a day are ultradian, periods longer than a day are infradian, and those with periods close to an hour are circadian. There are also complex clocks that combine mechanisms and period length as in sleep (Harfmann et al. 2015).

### Hourglass Clocks

Development, puberty and ageing have species dependent, predictable durations. These clocks play important roles in coordinating cell division and differentiation related to growth and senescence. Once triggered, hourglass clocks run out their cycle and do not reset. Many mechanisms are currently under investigation including telomere length. Telomeres are repeating sequences at the end of DNA strands that do not code for protein and protect the sticky ends of DNA from joining. Telomeres are long in young animals and, as they are incompletely replicated during cell division, become shorter with age correlating with gestation and ageing. Elongation of telomeres increases the life span of transgenic animals supporting a role for telomeres as count down/hourglass clocks in animals (Rensing et al. 2001). The role of telomeres in development and ageing of plants is less clear (Watson and Riha 2011).

### Embryogenesis and the Developmental Clock

Embryogenesis – the progression from egg to organism is a complex series of events many of which occur at predictable times suggesting orchestration by a developmental clock. The creation of somites – precursors for bones muscles

and tissues in segmented organisms – is the best described. Somite formation occurs in waves – with species-specific periodicity that is determined by oscillating genes within presomite tissue. Perturbation of the oscillations disrupts development and results in the loss and fusion of vertebrae and ribs. Cells within a group must be synchronized for proper development of the somite. Neuronal cells differentiate in response to the rhythmic release of HES-1 – a transcriptional repressor that promotes neuronal proliferation. HES-1 is regulated by a molecular feedback loop. As it is not clear, if the period can be adjusted or synchronized more work must be done to determine if this process is driven by a clock (Webb and Oates 2016).

### Epigenetic Clock and Aging Correlation

Age is defined by the decrease in homeostatic mechanisms that negatively alter gene expression and molecular pathways, causing tissues to age. Though aging is largely affected by genetic influences, DNA sequences and telomere length, epigenetic influences carry a significant amount of weight. Epigenetic mechanisms can alter DNA methylation, posttranslational histone modifications and non-coding RNA. First, DNA methylation is necessary for development because of its role in cell fate determination; there is an overall decrease in DNA methylation as individuals age. DNA methylation also shows involvement in genomic imprinting, female X-chromosome inactivation, and gene silencing. Second, posttranslational histone modifications involve eight histone marks (acetylation, methylation, phosphorylation, etc) that regulate gene function. Modifying these histones consequently remodels chromatin and, ultimately, gene expression. These posttranslational histone modifications are also found to alter the aging process in worms and *Drosophila*. Third, non-coding RNA are also known to be involved in aging and have been found to be altered throughout the aging process. For example, microRNAs (miRNAs), short non-coding RNAs, are involved in the repression of gene translation. Because they are necessary for growth and development, the malfunctioning of miRNAs can lead to disease. Overall, the accumulation of

these epigenetic mechanisms significantly impacts the aging process (Huidobro et al. 2013).

### Seasonal Hourglass Clocks

Many species respond to the seasons with changes in reproduction, coat color, and hibernation (Paul et al. 2008). Vertebrates with relatively short life spans (i.e., a year or so) seem to use interval timer triggered by day length to initiate and reset their cycles. For example: syrian hamsters maintained on photoperiods with less than 10 h of light per 24 h experience testicular regression over 10–12 weeks. Prolonged exposure (i.e., more than 14–16 weeks) renders the animals insensitive or refractory to the daylength and the testis return to their original size and function. Exposure to long days resets the clock so that reexposure to short days once again induces regression. In vertebrates, this version of infradian clock requires an intact circadian system and melatonin.

Several mechanisms have been proposed including: an internal coincidence model in which seasonal changes are induced by light induced, changes in the relationships of internal circadian oscillators, and an external coincidence model in which seasonal changes are induced by light falling on photo inducible phases of the underlying circadian rhythm.

## Oscillatory Clocks

True biological clocks are characterized by: their persistence in the absence of time cues, their ability to be synchronized by periodic external cues and their resistance to changes in temperature. The best known clock is the circadian clock which directs rhythms with periods of about 24 h. There are also clocks with longer periods (infradian) that regulate monthly and seasonal rhythms and those with shorter periods (uniradian) that regulate hourly burst of activity. Interestingly, the circadian system is involved in these clocks as well.

### The Circadian Clock

Circadian rhythms are found in every cell and every species, waxing and waning with the

minutes and hours of the day. These rhythms underlie our ability to tell time, to coordinate our activity with the sunrise and sunset and the changing seasons. Deficits in the circadian system may influence susceptibility to disease, productivity at work, and attention (Turek 2016).

In vertebrates cellular clocks are synchronized and coordinated by neural elements. For example, the Suprachiasmatic Nucleus (SCN) houses the biological clock that synchronizes rhythms in homeostatic mechanisms and behavior (Sollars and Pickard 2015). The SCN receives input from specialized cells in the retina that synchronize its rhythms to external light cues and maintains connections with the hypothalamus and pineal gland to regulate a variety of functions. Transplantation of the SCN into the hypothalamus synchronizes rhythms – restoring behavioral rhythms (wheel running) without direct innervation suggesting that chemical messengers – neurotransmitters and hormones – must be involved (Brain Research Reviews 33 (2000) 34–77 [www.elsevier.com/locate/bres](http://www.elsevier.com/locate/bres) Full-length review The suprachiasmatic nucleus and the circadian time-keeping system revisited a b a, Lisette (K.) E. van Esseveldt, Michael N. Lehman, Gerard J. Boer\*). The pineal plays a critical role in birds and reptiles – transplantation of the pineal can restore rhythms in arrhythmic sparrows (Zimmerman and Menaker 1979).

The circadian clock is regulated by a negative feedback loop that is maintained by the oscillation of the core clock genes, transcriptional factors that govern negative and positive feedback loops (van Esseveldt et al. 2000). Genes that govern this 24-h internal clock are referred to as clock genes: *Bmal1*, *Clock*, *Per1/2* and *Cry1/2*. A significant example of the internal clock at work can be noted in skeletal muscles, which make up about 45% of the body's total mass (Harfmann et al. 2015). 2300 genes in skeletal muscle are involved in the expression of circadian rhythms, which drive the functioning of this clock. Skeletal muscles are directly stimulated through feeding and activity but also indirectly through light entry into the SCN. This mechanism is synchronized with the rhythms of the environment and other issues of the body. When circadian rhythms of skeletal tissues

are disrupted, the structure of the sarcomere is changed; there is a decreased mitochondrial respiration rate and, ultimately, the muscle function is altered.

### Infradian/Lunar, Semilunar and Tidal Clocks

As noted by fishers, throughout the centuries many marine organisms utilize the cycles of the moon to regulate reproduction and growth. The nature of these clocks varies by species. For example, reproductive maturation of the marine worm *Platynereis dumerilii* is regulated by a circalunar clock that is synchronized by a circadian clock (Zantke et al. 2013), while the lunar rhythm of spawning in the Goldlined spinefoot fish is set by an hourglass clock (Takeuchi et al. 2018). Interestingly, the foraging behavior in the intertidal isopod, *Scyphax ornatus*, is regulated by the “beat frequency” created by the intersection of circadian and tidal rhythms (Cheeseman et al. 2017).

### Infradian/Seasonal Clocks

Species that live for many years in temperate climates show changes in physiology and reproduction that persist in constant conditions with periods close to a year. These rhythms can be synchronized to the external seasons with daylength and maintain different periods depending on the length of day they are exposed to indicating the existence of a circannual clock. A putative circannual clock has been identified within the pars tuberalis of seasonal vertebrates. This area of the pituitary contains thyrotrophs that lack receptors for thyrotropin releasing hormone. These PD-specific TSH cells show seasonal changes related to the production of the clock-regulated transcription regulator (EYA3). EYA3 induces TSH expression triggering long-day responses in birds and mammals (Wood and Loudon 2018). The PD-TSH cells contain melatonin receptors and are driven by melatonin which, in turn, is driven by the circadian system.

### Ultradian Clocks

Very short oscillations (2–4 h) in feeding and activity bouts have been identified in a number of species including, hamsters, voles, mice, and

deer. While the function of these rhythms is not clear – researchers have speculated that ultradian rhythms function to coordinate bouts of feeding in the wild providing safety in numbers. Ultradian rhythms correlate with circadian rhythms but are not dependent on them. Manipulations that alter circadian periods also lengthen ultradian periods. Nonetheless, ultradian rhythms persist under conditions that abolish circadian rhythmicity. For example, ablation of the SCN enhances ultradian rhythmicity indicating that the oscillations are not driven by the SCN. Ablation of the arcuate and the retrochiasmatic area abolishes ultradian rhythmicity suggesting a critical role for this area.

Several lines of evidence suggest that Dopamine may also play a role. Dopamine is released into the striatum (a key component in locomotor activity) in bouts that correlate with ultradian rhythmicity and manipulations that lengthen or shorten these bouts create parallel changes in ultradian periods suggesting that the VTA/SN may also be involved. Finally, it should be noted that a number of hormones are released in bursts. Ultradian rhythms are also present in a number of hormones including those that regulate reproduction, growth, and stress. Changes in the frequency of gonadotropin releasing hormones drives reproductive activity; changes in the pulsatile delivery of glucocorticoids is correlated with a number of diseases including: Alzheimers, anxiety depression, and PTSD (Prendergast and Zucker 2016).

## Sleep and Interval Timing

The regulation of sleep has been intensely studied and is still largely a mystery! The onset of sleep is determined by the circadian clock – we are sleepy at times readily predicted by the rhythms of alertness and our core body temperature. How long and how deeply we sleep appears to be dictated by an hourglass clock that is phase-locked with the 24-h biological clock but varies depending on the previous night's length of sleep. Sleep and interval timing are significantly connected mechanisms. One of the main functions of sleep is thought to be synaptic plasticity. Sleep acts as a mechanism for memory consolidation. This can

occur after a few minutes, hours or full night's sleep (Tucci 2012).

The connection between circadian rhythms and interval timing is not well-known. Some studies show that interval timing is dependent upon oscillatory mechanisms, noting a close relationship between these two entities. For example, studies have shown that circadian rhythms, which are longer, can alter shorter intervals, which can be seconds or minutes in length. On the other hand, other studies suggest that interval timing and circadian rhythms are separate entities, through SCN lesion studies and studies of interval timing in mice with arrhythmic circadian rhythms (Tucci 2012).

## Clocks and Disease

Several disorders can result from disruptions to the circadian clock. (Disruptions in circadian rhythmicity induced by shift work and jet lag have been linked to disorders of metabolism and the immunity that predispose diabetes and cancer.) Mental health disorders such as major depressive disorder and seasonal affective disorder appear to result from endogenous factors that misalign the circadian system with the external environment. More recently studies suggest that alzhiemers may desynchronize the circadian system, rendering it more susceptible to other disorders. Far less is known about how hourglass clocks contribute to our health and as hourglass timers regulate development and ageing – more attention should be paid to these systems (Bass and Lazar 2016).

## Internal Fertilization

Qurat Ul Ain Reshi

Department of Pathophysiology, University of Tartu, Tartu, Estonia

Internal fertilization is the process in which fusion of male and female gametes occur inside the body of females. Internal fertilization is most common in land-based terrestrial animals, but few aquatic animals also employ this mode of fertilization. Fertilization refers to the amalgamation of haploid male and female gametes (sperm and oocyte) in a series of well-coordinated molecular events, which eventually leads to the formation of diploid zygote. Fertilization leads to the merging of genetic material within the species, which results in genetic variation in the organisms. In sexual reproduction, two modes of fertilization have been noted in animals – internal fertilization and external fertilization. In internal fertilization, the amphimixis (fusion of male and female gametes) process occurs within the body of females, and the zygote starts developing inside the mother's body. Under external fertilization, the union of eggs and spermatozoa occurs outside the female body in a medium like water where the concerned animals reside. In this entry, we will be discussing internal fertilization in more detail. Internal fertilization which is often seen in land animals has three types:

1. Oviparity: The fertilized eggs are laid outside the female's body and develop there; yolk part of the egg serves as the source of nourishment.
2. Ovoviviparity: The fertilized eggs are retained in the female, and the embryo fulfills its nourishment requirement from the egg yolk.

3. Viviparity: The embryo formed develops within the female and receives its nourishment from the mother's blood through a placenta.

The significant events which take place during the process of fertilization include copulation and insemination, transport of sperms, binding of the spermatozoon to the egg, induction of acrosomal reaction by spermatozoa, and fusion of spermatozoon and egg which ultimately results in a diploid zygote. All these events require excellent coordination between all the key molecules involved in this intriguing process.

Millions of spermatozoa travel through the cervix, until some of them successfully reach oocyte, and in this course of the journey, many of them die due to the acidic environment, innate immune responses by the female reproductive tract. Spermatozoa undergo the process of capacitation by which they attain functional maturation in the fallopian tube (Ickowicz et al. 2012). Once spermatozoa attain capacitation, they become hypermotile and move toward the oocyte. Capacitation involves alterations in the phosphorylation state of proteins, a rise in intracellular pH and calcium levels and hyperpolarization of membrane potential. An exocytotic event occurring after capacitation is acrosomal reaction, which is another prerequisite for fertilization to occur. It makes a spermatozoon capable of penetrating the zona pellucida layer of the oocyte (Crozet 1994). Izumo, a kind of protein, specifically present on sperm, plays a pivotal role in binding and fusion of sperm and egg plasma membrane. A member of the folate receptor family, Juno, recognizes IZUMO, which is followed by fertilization taking place. The fusion between oocyte and spermatozoon causes the cessation of the beating of the tail by the spermatozoon. Sperm is drawn into the oocyte by the elongation and fusion of the microvilli of the egg, and this leads to the incorporation of sperm nucleus and other organelles into the oocyte cytoplasm (Georgadaki et al. 2016). The membrane of oocyte undergoes depolarization massively after fertilization. This depolarization is achieved by the influx of plethora of  $\text{Na}^+$  ions depolarization of the egg is followed by repolarization via  $\text{K}^+$

**Internal Fertilization, Fig. 1** Schematic illustration of spermatozoa traveling through the fallopian tube, from isthmus making its way toward ovum, which lies in the ampulla region of the fallopian tube. Spermatozoon

interacts with the zona pellucida, and this interaction leads to changes in the zona pellucida as a result of which other spermatozoa are not able to interact with the ovum, thus inhibiting polyspermy

leakage, which induces fast block polyspermy and the sperm is not able to fuse membrane that is not  $-70$  mV. A permanent barrier is established for sperm entry by cortical reaction which propagates over the egg surface (Gilbert 2000).

Internal fertilization has certain advantages over external fertilization as a mode for reproduction in animals, which includes the protection of young one against predators, thus increasing the chances of survival; the probability of successful fertilization is much higher in case of internal fertilization versus external fertilization, and the dehydration of gametes is also prevented in case of internal fertilization. Moreover, internal fertilization is less demanding in terms of resource expenditure along with greater survival chances of young ones. However, in internal fertilization male and female has to be in intimate contact for game transfer and under this process limited number of offspring are produced as compared to external fertilization. Additionally, in internal fertilization chances of sexually transmitted diseases pose a risk to copulating individuals in all animal species, which is not the case in external fertilization (Fig. 1).

## Introduction

Reproductive traits are those parameters that are most influenced by evolutionary change. There are several evolutionary forces like genetic drift, mutation, and natural selection that become threat

to the survival of any species. Males and females both change their mating behavior in accordance to the prevailing environment so as to adapt and increase their survival and fitness. Males and females have varying strategy for achieving reproductive fitness. According to Bateman's principle (1948), female produces very less number of gametes that constitute enormous proteins and other biomolecules as compared to the male gametes that are smaller, numerous, and not so nutrient enriched either. Female gametes are therefore more costly than of males and consequently females becomes a limiting sex. So there is a tendency in males to compete for maximum number of females for mating and inherit maximum number of progenies to increase their fitness, while females choose the best male which will bore them the fit progeny. Females have more parental care roles besides reproduction, and as a result females throughout all species are very selective for choosing mating partners. This creates an antagonistic coevolution and causes high competition among males to possess maximum elaborative features. Choosing mates on the basis of sexual and other reproductive traits in one sex by the other causes intersexual competition, and its permanence during the course of evolution leads to intersexual selection.

Females ascribe their fitness to certain parameters present in males such as territorial quality, food, or decorative phenotypes. There are enormous examples of mating behavior displayed by males displaying such attributes to attract females. Charles Darwin and Alfred Russel Wallace first gave the concept of attracting mating partners by males through specific behavior, e.g., mating calls in frogs by croaking at the water's edge, and then the female chooses the male with the deepest croaking sound and territorial quality so that it would pass to her progeny and by that she can have maximum grandchildren. According to Richard Dawkins (1976), females that prefer long and attractive tailed males tend to have mothers that have the same trait of choosing such males, and therefore female progeny carry two traits, one the preference for long tail and other to bear such trait so that it will pass to her son. So in nature these two traits are linked with

each other and both have positive correlation with each other. According to Bateman's principle, female when searching for mate keeps rejecting males that she considers unsuitable for her, and then such males are unable to pass their genes in nature, while for female the risk of dropping such "unfit" males is lower than investing time and resources in searching for the attractive and fit male. So according to Bateman, the sex whose main objective is to produce the most fit progeny and choose mates accordingly becomes the limited sex for which other one competes. Males reside in intense competition in possessing these parameters better than others and strive for access to maximum number of females. This can be a very strong reason for why modification brought in secondary sexual characteristics is predominantly in males.

So it drives species through adaptation responses toward mate choice (Darwin and Wallace 1858). This sort of mate choice is called as sexual selection, and it leads to sexual dimorphism in secondary sexual characteristics in both males and females. The presence of elaborate and colorful tail feathers in male peacock manes in lions, antlers in deer and songs in birds during breeding seasons, difference in body color between males and females in birds, larger body size of males in Cichlid fish *Neolamprologus callipterus*, black-throated blue warblers and Guianan cock-of-the-rocks that also differ radically in their plumage between the sex are the various examples of this observable fact. Sexual selection is also found in plants and fungi (Moore et al. 2011).

Intersexual selection creates genetic variation and thus more fit generations are produced. It is mainly caused by presence of intrasexual competition among males. Factors influencing male intrasexual competition are cases where food, habitat, and mates become a limiting factor which leads to aggression among males. In male-biased sex ratios, even small males take the risk of fighting with larger male in the presence of female for mating opportunities. These sorts of conditions put pressure on males to modulate their mating behavior and on secondary sexual characteristics, i.e., phenotypic traits to increase their fitness.

**Intersexual Fitness:** This is defined as achieving fitness by male or female at the cost of the others' lifespan. Usually males perform more matings than females, and it decreases longevity of the former, while females are found to be adaptive toward increased matings. Male harm females either physically like traumatic insemination, forced copulation, love darts, etc. or physiologically like transfer of accessory proteins, e.g., in *Drosophila* that would decrease female's longevity. Females too evolve counter-adaptations in order to protect themselves from frequent matings. In some species females respond by various means like sexual cannibalism and increased aggression to males (e.g., praying mantis).

## Sexual Conflict

Sexual conflict is a specific type of evolutionary conflict that occurs when males and females have evolved different reproductive behavioral strategies to gain fitness (Parker 2006). This conflict leads to evolutionary arms race due to the mode of reproduction in each sex that harms the other one to achieve fitness (Lessels 2006). There are cases of sexual conflict, for example, where male dominance is found as in wolves, rabbits, and crocodiles and female dominance like spiders, ants, and orcas. In species which are male dominated, males are usually polygamous and larger in size, possess high reproductive success, and have less or no parental care, while in female-dominant populations, females are larger in size with high fitness and prefer mates only on the basis of territorial, habitat, or food offered to her by the male before mating. Therefore sexual conflict is a factor that makes evolutionary changes in both the sexes. In *Drosophila*, e.g., males displace the previous mated male's sperm and transfer biochemical metabolites that enable the female to remate for some time interval. Males also show aggressive behavior toward other males in the form of male-male combat and toward female in the form of mate guarding or forced copulation. They behave in these manners in order to assure their paternity success. Morphological adaptations in males toward competition include development

of male claspers, altered genitalia (e.g., spiky genitals), and copulatory plugs (*Lacerta monticola*). The level of intrasexual competition for mates also affects the anatomy of reproductive glands, seminal vesicles, and interior prostates. Sexual conflict before and during mating comprises following aspects:

**Infanticide:** Some animals also perform infanticide. In this case mostly males used to cause damage to their eggs or kill their young ones to increase its fitness. The advantage gained by this is that the parent, who is providing care to the eggs, after the destruction of eggs or death of the offspring, will be available for mating with the destroyer male or female individual. Examples of such cases are found in big cats, *Jacana jacana*, and mice.

**Traumatic insemination:** In this type of mating behavior, male used to penetrate his genitalia inside females reproductive tract, forcefully in order to ensure paternity success. This is called traumatic insemination. In some cases it leads to death of the female, e.g., bed bugs and spiders.

**Physiological barriers:** In *Drosophila melanogaster*, males used to transfer toxic semen that contains accessory proteins to the mating female that hinder her lifespan. In *Drosophila hibisci*, males used to create mating plugs in female to provide nourishment to her besides preventing the sperm of rival male to fertilize the female.

**Aggression:** Males in many species commit force copulation with female in which they do harassment and grasping. In harassment, male chases female and annoys her from distance. In the case of Malabar ricefish, when the male observes that female is ready to copulate, it attacks her from distance and releases his club-shaped organ inside the female which causes harm to the female. Males perform grasping in order to avoid the female to be mated by rival male and ensure his paternity success. The resistant female is able to remove the male from her side, but the female which is not so strong becomes unable to move due to the weight of the male attached to her.

*Sexual cannibalism*: It includes the consumption of the mating male by the female partner in order to increase the quality of her offspring by receiving nutrients from the consumed male. Males sometimes manipulate females and use their strong appetite to their advantage by giving them edible gift of another males to protect themselves from being eaten, e.g., funnel-web spider (*Hololena curta*).

*Antiaphrodisiac*: In this behavior males transfer certain chemicals to females that are only produced in males and which let other males to identify individuals as males. So when these chemicals will be transferred to females, other males will consider them as males and will avoid any mating. This will help the male that had first mated with the female to reduce competition for mating and secure its paternity.

## Theories on Evolution

Evolution of male secondary sexual characters and other ornamental features can be attributed to choosiness of female in selecting elaborative males who pretend to be more fit and capable of raising “superior sons” and increase fitness in females. Males too evolve by deceiving females of their fitness traits and attracting maximum of them and then causing harm to them.

*Good Genes Theory*: This theory is termed as the sexy son hypothesis and was first proposed by Weatherhead and Robertson (1979). According to this hypothesis, females prefer to mate with those males that mostly produce male offspring and that too of high reproductive success. Ronald Fisher (1930) gave the term “sexy son hypothesis” which means that females tend to mate with those males that possess attractive phenotypic features and will produce alike sons with elaborative traits. It may be a reason why only such peacocks are observed today that have elaborative feathers because this trait had been selected in nature due to the preference of such males over others that lack such traits. Females in all subsequent generations that had inherited these qualities of preferring such males and continued reproducing sons and daughters from such mating allow selection of

these traits in nature creating “Fisherian runaway sexy son process” (Mead and Arnold 2004). This creates a condition of assortative mating or homogamy in which individuals who are alike prefer to mate with each other and lead to the survival of individuals which have similar genotypes and phenotypes.

*Zahavi's Principle*: This theory was first postulated by Zahavi, 1975. According to this theory, males in certain species show traits that negatively affect their fitness, and therefore they signal that in spite of possessing elaborative and costly features that hinder their fitness and other life history traits, they are carrying it with ease. So it signals that males that carry such traits are more fit, females chooses these males because they consider them to be strong and hence prefer them over other males to produce such sons which will have such traits.

In 1984, W. D. Hamilton and Marlene Zuk proposed a theory of “Bright Male” according to which females consider males with exaggerated features as they consider them to be resistant toward diseases and deficiency and therefore fit to mate.

## Sex-Biased Gene Expression

Sexual dimorphism is due to selective expression of certain genes in different environmental conditions in both males and females. The role of natural selection on the sex that expressed maximum of the characters required to achieve fitness or subjected to sexual selection amidst of intrasexual competition and mate choice can be attributed to difference in gene expression (Ellegren et al. 2007). Sexual antagonism is another concept that creates sex-specific gene expression due to the occurrence of sexual conflict that leads to evolutionary arms race, i.e., when certain competing set of genes coevolve. This gives rise to selection of these genes in males and females differentially at single or multiple locus and eventually selection of those locus that are antagonistic in one sex to the other. These loci carry genes that enhance certain traits in one sex and suppress the same in the other one. This helps in retaining all alleles in

both sexes and thus evolves interlocus sexual conflict (Partridge et al. 1998). There are genes in X chromosomes and autosomes that represent traits that are antagonistic to the opposite sex in the animals worldwide. They can be present on autosomes, and their expression can be either sex limited or absent but harmful for the other sex. In *D. melanogaster*, there are antagonistic genes present on X, second, and third chromosomes.

## Sexual Dimorphism

It occurs in different forms like size, weight, color, markings, and behavioral and cognitive differences. These differences are selected in nature when they are beneficial for the species during the course of evolution. There are following attributes of sexual dimorphism:

*Ornamentation and coloration:* Ornamentation and coloration are a form of sexual dimorphic trait which is found in birds and reptiles. When animals carry these traits in which mostly are males, they have to compensate its costs while carrying and maintaining it while increasing its fitness at the same time, e.g., peafowl, birds of paradise, and argus pheasants. In the case of nestling blue tits, males develop violet-tinted plumage because they feed on lepidopteran larvae, which contain large amounts of the carotenoids, lutein and zeaxanthin. Females prefer such males because blue-colored plumage is an indicator of male parental abilities and that it is capable of obtaining carotenoid and thus has strong immune function.

Females prefer males which possess brightly colored features against males that appear pale and dull, and one example is male guppies which possess colorful spots and ornamentations, while females are generally gray in color. Males with colorful spots are preferred over males that don't possess such.

*Physiological differences:* In redlip blennies, male fish develops an organ at the anal-urogenital that produces antimicrobial substances and protects egg from microbial infections.

*Spiders and sexual cannibalism:* In spiders and insects like praying mantis, there is selection for large body size in females for mating by males because such females avoid eating the male before copulation and males therefore prefer to mate with females that are feeding at the time of courtship or they modify the female's web or provide a nuptial gift to them in the form of a dead insect so they are escaped from death.

*Fish:* In fishes, mostly females are larger in size than males, but wherever males have more parental care role, they are found to be larger, e.g., *Lamprologus callipterus*. In this females choose larger males because they will be able to collect maximum empty shells and females need these shells to lay their eggs and if female are larger than a limit, it will not fit in the shell and will be unable to breed. Choosing larger males allows female to join its brood and allow itself to increase its size because that male can collect large shells. Male-male aggression and combats are also responsible for male's large size to increase the access to maximum number of females. Another example is dragonet, in which males are larger than females and possess longer fins.

*Amphibians and reptiles:* In reptiles there is a wide range of sexual dimorphism observed across taxa. It differs in various traits in anatomy like relative length of tail, relative size of head, overall size (e.g., vipers, lizards), coloration (e.g., amphibians, snakes, and lizards), ornamental features (e.g., newts and lizards), and morphological and physiological differences (e.g., frogs). Male coloration in dragon lizards *Ctenophorus pictus* is an indicator of innate anti-oxidation capacity to females that protects against oxidative DNA damage (Olsson et al. 2012).

*Birds:* Sexual dimorphism in birds can be observed in size and plumage differences. Generally males are larger than females except in some cases like birds of prey, hummingbird, and some species of flightless birds (Andersson 1994). Plumage dimorphism varies among the birds which depend upon

the role of males in raising the younger one. If the male contribution is only limited to mating and copulation, then these males' plumage is more vibrant than those who take care of their young ones by defending and feeding them. Birds acquiring vibrant features have to pay its cost by becoming more conspicuous to predators and putting their life in danger. So long as the benefit of these attractive features in increasing their fitness is more than the cost of losing life, these features are selected in nature and propagated by enormous number of young ones produced by attractive males.

**Mammals:** In mammals males are always larger in size than females, and it is due to the effect of reproductive hormones that play a role at early stages of embryonic development. This difference in size is due to presence of more male aggression, defending the mate and involvement in parental care.

**Reproductive advantage:** In maximum number of cases, females are larger than males because during the course of evolution, female has this load of producing maximum young ones and male must search for females while females tend to be sedentary. This also led to selection of distinct morphometric and physiological traits in both the sexes.

Intersexual selection is thus driven by intersexual conflict that persists in almost each taxon of animal kingdom. It involves modification in mating, phenotype, and physiological aspects in both the sexes but predominantly in males because they should display all such characters to increase their fitness, while for females they are the costlier and choosier sex. In all groups where males are involved in less parental care, they either are more attractive or show distinctive mating calls and territorial ability, aggression, and manipulation. In species where the mating pair is monogamous in nature, there is very less difference between sexual dimorphism between male and female, e.g., sandhill crane, seahorse, gray wolf, barn owl, gibbons, black vultures, and beavers. So it clearly indicates that occurrence of gender roles

creates various types of sexual conflict and leads to intersexual selection.

## Interspecific Brood Parasitism

Joseph F. Di Liberto

University of California, San Diego, CA, USA

### Definition

A breeding strategy in which one species is able to manipulate a different host species into forfeiting some or all of their parental investment into rearing the parasite's offspring. This often coevolutionary relationship is a potential source of evolutionary arms races as species develop increased measures to defend reproductive investment in the case of hosts, or for parasites, to more successfully ensure host compliance.

### Introduction

For many species, the process of reproduction is a period of high-energy investment with profound consequences for organismal fitness, and in ideal mitigation of these costs, an unusual breeding strategy has emerged. Interspecific brood parasitism (IBP) is a breeding strategy in which a parasitic species seeks to exploit the reproductive investment or parental care of another host species for their own offspring's benefit. This breeding strategy often elicits vivid relationships among parasites and hosts: a Superb Fairywren (*Malurus cyaneus*) feeding what it believes to be its offspring; a begging Bronze Cuckoo (*Cacomantis variolosus*) chick multiple times its size (Langmore 2012); a Large Blue butterfly (*Maculinea rebeli*) caterpillar receiving royal treatment and from an *Myrmica* ant colony after mimicking the ant queens' movements and scent (Akino et al. 1999); a mouthbrooding African lake cichlid providing food and shelter for Cuckoo Catfish (*Synodontis multipunctatus*) offspring from the inside of its own mouth (Sato 1986).

Parental care is widely known to be highly impactful in improving offspring survival, but this is not without cost (Clutton-Brock 1991). Behaviors such as offspring defense, nest

building, and food provisioning are activities that are highly time- and energy-consuming and may often imply an increase in predation risk for the parental individual (Trivers 1972; Roldán and Soler 2011). Considering these costs, the ability for a parasite to bestow costly parental duties onto another, unrelated species can be a high reward to the parasitic individual allowing for more time and energy to gather resources, avoid predators, and even, theoretically, to have more offspring (Payne 1977; Rothstein 1990). By engaging in this form reproductive behavior, these brood parasites can gain a variety of benefits for them and their offspring including nest usurpation, theft of stored resources, exploitation of eusocial worker labor, or even gaining complete care and provisioning by the host species (Soler 2019). Consequently, a host that plays into supporting or raising a completely different species than its own is a major detriment to the host's fitness usually through the diversion of resources away from the host's own young. However, if the care of parasitic offspring imposes such a great burden to the host or if the parasite eliminates the host's own offspring completely, the breeding success of the host diminishes to zero (Kilner and Langmore 2011; Feeney et al. 2014; Soler 2019). These drastic costs to host fitness are what often leads to the evolution of reciprocal host defenses to avoid being parasitized and these may include such strategies as parasite egg rejection, increased vigilance, nest site selection defense, and even nest abandonment (Soler 2019). This basic framework of parasite and host species evolving to select for adaptations that better appropriate or defend valuable reproductive investment is responsible for the well-documented and studied, coevolutionary "arms race" that may develop (Feeney et al. 2012).

In spite of the seemingly contrived nature of IBP, the breeding system itself is rather widespread phylogenetically, occurring across multiple lineages in birds, insects, and fish. Given this widespread and often visible nature, IBP has, and continued to be, a topic of persistent research across a multiple biological subfields. To that end, the abundant and diverse literature on IBP has become filled with systematics, models, and

theories to best explain the taxonomy of interspecific brood parasites, how IBP arose evolutionarily, and the diverse adaptations of parasites and hosts that have come to characterize this breeding strategy.

## Taxonomy of IBP

Across the animal kingdom, forms of brood parasitism are presumed to be rather common in species that exhibit parental care (Soler 2019). Although interspecific brood parasitism in particular is also widespread, it is more restrictive, with the only known species engaging in IBP being insects, birds, and fish.

The most widely known and studied cases of interspecific brood parasitism occur in birds. Within this group, IBP is found within 4 orders of the 40 orders of birds worldwide—Anseriformes (Family Anatidae), Cuculiformes (Family Cuculidae), Piciformes (Family Indicatoridae), and Passeriformes (Families Viduidae and Icteridae) (Mann 2017). Among insects, interspecific brood parasites are most common in social hymenopterans such as wasps, bees, bumblebees, and especially ants. Although concrete numbers for interspecific insect brood parasites are more difficult to estimate due to the volume of potential candidate species, there are more than 200 described species in eusocial ants, the best studied of this group (Soler 2019). The only other known cases of interspecific brood parasitism are found within the cichlid fish family: the Cuckoo Catfish (*Synodontis multipunctatus*) and the Sapuwa (*Bathyclarias nyasensis*) (Sato 1986; Stauffer and Loftus, 2010).

## IBP Evolution and Coevolution

In spite of its known and presumed abundance within many insect clades, the evolution of IBP in insects has been largely neglected (Buschinger 2009). However, given that many parasitic species and their hosts are close phylogenetic relatives, some have speculated that IBP in insects has evolved many times independently (Buschinger

2009; Soler 2019). However, given that some insects engage in IBP across of orders, such as in the caterpillar of the butterfly's (*Maculinea rebeli*) parasitism of *Myrmica* ants, there must be even more profound changes to the parasites' life history, physiology, and ecology (Akino et al. 1999). The complexities between these kinds of changes has made the prospect of gaining a clear consensus on IBP's evolution in insects an intriguing challenge for further studies.

Generally speaking, avian brood parasites have received the most attention and through examination over the years, and while a clear consensus on the evolution of IBP within this group has not emerged, the plethora of studies on avian IBP has lent itself to multiple perspectives on the origins and maintenance of this breeding strategy. Most theories regarding the evolutionary origins of IBP have suggested that IBP emerged later in species that had already been engaging in conspecific brood parasitism (CBP) (Lyon and Eadie 2017). This had been reasoned through the idea that due to CBP also alleviating parental care costs, parasitic species engaging in CBP may have been more likely to use this strategy without significant negative effects. Particularly in populations with many individuals partaking in CBP, parasitizing other similar species' nests could have developed as another option to retain the benefits of parasitism while not being constrained to find conspecific hosts (Lyon and Eadie 2017). However, other studies have used phylogenetics to conclude that CBP and IBP are not necessarily as closely linked, suggesting that the state of parental ancestral care can lead to brood parasitism without explicitly requiring CBP to act as a precursor (Krüger and Pauli 2017). Multiple other factors, such as cooperative breeding, increased nest predation, and nest site competition, have been suggested as potentially favoring the evolution of avian IBP, but unanimous support for any of these factors, among others, has not been achieved (Feeney et al. 2012; Soler 2019).

When examining the evolution of IBP, it is imperative to also take into account the coevolution of host defenses as these crucial, reciprocal adaptations play an equally important role in the

commonly associated evolutionary arms race between parasites and hosts. This basic arms-race framework has been dissected and expanded upon in recent years to better explain how these interactions may have further developed into the brood parasitic relationships observed (Feeney 2017). One of the most successful modalities of understanding this coevolution is through the division of the coevolutionary arms race into a complex sequence of coevolutionary stages in which no stage of defense is independent of each other, and, in which the arms race between parasites and hosts functions on each level (Soler 2019). To that end, a successful adaptive defense at any stages of the breeding cycle would prevent the evolution of later lines of defense, and successful resistance by a host can be achieved with one or more successful defenses at any stage of the breeding cycle. These stages in which the coevolutionary arms race functions on parasite and host adaptations are: the pre-laying stage, the egg stage, the nestling stage, and the fledgling stage.

## Adaptations and Counter-Adaptations Through Coevolutionary Stages

### The Pre-laying Stage

The first opportunity parasites and hosts to develop strategies and defenses is before the egg is even laid, and the interactions in the pre-laying stage have become known as “frontline” defenses (Feeney et al. 2012). During this stage, hosts can utilize a variety of different tactics to avoid being parasitized that include asynchronous breeding phenology (Medina and Langmore 2016), nest concealment or placement (Hauber and Russo 2000), attacking or mobbing known parasites (Feeney et al. 2012), among others. At this stage, parasites have also evolved certain strategies in order to combat these frontline host defenses. Many studies have focused on the cognitive adaptations that have been seen in certain avian brood parasites that have allowed them to circumvent some of the pre-laying defenses of hosts. These include increased spatial memory in females, assessment of host readiness, and the modification

of nest searching strategies in relation to host availability (Guigueno et al. 2014; Jelinek et al. 2014). Parasites may also use deceptive camouflage as well as to cryptic behavioral and movement patterns to spy on susceptible hosts and lay eggs quickly and discreetly in unguarded nests (Feeney et al. 2012; Langmore 2012). Lastly, it has been shown that one commonly studied brood parasite, the Brown-headed Cowbird (*Molothrus ater*), may tactically destroy hosts found too far into the breeding cycle. This “farming” behavior forces hosts to renest, potentially increasing available nest sites in the future (Swan et al. 2015).

### The Egg Stage

If the hosts’ defenses fail at the pre-laying stage and the brood parasite is able to lay an egg in the host’s nest, another arms race can be said to occur at this stage, also known as the egg stage, of the breeding cycle. Over the years, many studies have examined what is perhaps the most widespread and effective host defense against brood parasitism: the rejection of parasitic eggs (Soler 2019). Although egg rejection is known to have a genetic basis (Martín-Gálvez et al. 2006), factors such as egg-recognition ability, physical capabilities of the host species, and particular characteristics of the parasitic egg are all known to influence the actions of the host. Additionally, egg rejection is not without potential costs as incorrectly rejecting one of the host species’ own eggs or accidentally breaking the hosts’ own eggs during rejection has negative impacts on fitness (Soler 2019).

The rejection of parasitic eggs, especially of those between different species, is a complex cognitive process that has been, and remains, a topic of continued research (Bán et al. 2013). Two different cognitive mechanisms have been identified being key in this behavior: rejection by discordance, in which rejection is based off of the parasitic egg being a minority among the clutch of more similar eggs, and true rejection, in which the parasitic egg differs from the host’s own internal picture on what its eggs resemble (Bán et al. 2013). Once the host has discriminated and then chosen to reject an egg from its nest, there are four known ways in which it may do so: by burying the parasitic egg within the nest material, by

constructing a new nest on top of the clutch containing the parasitic egg, by deserting the parasitized nest, or by ejecting the parasitic egg (Soler 2019). Ejection of the parasitic egg is the most widely observed and effective defense among hosts with more than 60% of potential avian host species, even many not currently known to be parasitized, being able to eject a dissimilar parasitic egg (Soler 2019). Birds are physically able to eject the parasitic egg by grasping the entire egg with their bill or puncturing the eggshell and grasping the shell through the resulting hole (Soler 2019).

To avoid egg rejection or ejection, interspecific parasites have evolved a variety of counter-adaptations to better ensure that the host accepts the parasitic egg. Most of these counter-adaptations revolve around the evolution and production of eggs that are either difficult to distinguish in the nest, more attractive to potential hosts, or, are harder to eject or destroy (Davies 2011). Perhaps the most common evolutionary strategy that parasites use against egg rejection is egg mimicry: laying eggs that seek to ape the appearance of host eggs. A multitude of studies have demonstrated that host species tend to reject dissimilar eggs leading to parasites developing eggs that mimic the size, shape, color, pattern, and weight of their average hosts' eggs (Soler 2019; Davies 2011). Increases in egg mimicry elicits a strong evolutionary push for hosts to develop better egg discrimination abilities, which in turn, pushes parasites to select for more deceptive egg attributes (Davies 2011).

In addition to developing more similar egg attributes, interspecific parasites have used other tactics to enforce host acceptance of parasitic eggs. Certain avian parasites have been known to depredate the nests of noncompliant hosts that have rejected the parasites' eggs. This "mafia-like" behavior induces renesting in hosts, and upon subsequent parasitism, a higher potential for these hosts accepting the parasitic egg (Hoover and Robinson 2007). This is largely because, in this system, rejection may incur an increased cost for hosts when compared to accepting the parasitic egg. Due to the parasites' behavior, egg rejection will result in complete

clutch and nest destruction while acceptance provides at least the potential to retain some of the hosts offspring. Thus, the fitness costs imposed through these parasites' retaliatory behavior interestingly encourages selection for host acceptance of parasitism (Hoover and Robinson 2007).

### The Nestling Stage

While host defenses against parasitism at the pre-laying and egg stages of the breeding have been much more intensively studied, there has been considerably less research undertaken for potential adaptations at the nestling stage. This is because chick discrimination has largely been thought of to be a nonexistent or a weak defensive tactic against parasitism due to the high cost of incorrectly rejecting one's own chick, and relatively low concrete fitness benefits of rejection at this stage (Soler 2019). Furthermore, Lotem (1993) provided a strong model reasoning that nestling recognition tactics are less likely to evolve as the cognitive behavior of "mis-imprinting," or learning to recognize the parasite's offspring as the parents' own, exceeds the benefit of correct learning. In spite of these ideas, recent studies have found evidence for nestling rejection being a more viable possibility among host species. Studies on Australia's Superb Fairywren (*Malurus cyaneus*) have shown that these frequent hosts of various brood parasitic cuckoo species were able to reject cuckoo offspring by not provisioning the nestling or by abandoning the nest altogether (Langmore et al. 2003). As per the course of organisms involved in coevolutionary arms races, this adaptation has selected for parasites to develop counter-adaptations to prevent nestling discrimination. These adaptations have included parasitic offsprings' mimicking the appearance of host-nestlings, among other known adaptations (Davies 2011; Soler 2019). In fact, multiple mechanisms have been described as ways for parasitic nestlings to ensure compliance and procure increased parental care from their host parents. Some of these parasitic adaptations include the mimicry of host offspring's begging calls, more pronounced or conspicuous begging calls than the host's offspring, and integrating visual nestling displays (Soler 2019). All of

these adaptations are likely to select for more counter-adaptations that increase the competitive ability of host nestlings (Feeney et al. 2014).

### The Fledgling Stage

There is little information on the coevolutionary adaptations of hosts and parasites during the post-fledgling period of the breeding cycle. In spite of this, a few recent studies have determined that the coevolutionary arms race may indeed persist through this period. In Grayish Baywings (*Agelaioides badius*), potential host defenses at the fledgling stage can be observed in the provisioning behavior of parents; parasitic fledglings of one cowbird species – the Screaming Cowbird (*Molothrus rufoaxillaris*) – that mimics the begging behavior of the graywing offspring received provisioning while the fledglings of another parasite that does not mimic host offspring begging behavior – The Shiny Cowbird (*Molothrus bonariensis*) – did not receive much parental care (De Mársico et al. 2012). Another example of a potential host defense at the fledgling stage has been observed in Magpies (*Pica pica*). Magpies, the main host of the Great Spotted Cuckoo (*Clamator glandarius*), will feed parasitic fledglings only when the parasite is reared along in the nest; when a parasite is raised among the host magpie's own brood, the parent refuses to feed the fledgling (Soler 2019). Although evidence for parasitic counter-adaptations to these host defenses still remains scant, one study within the same magpie-cuckoo system determined that cuckoo fledglings from mixed-brood parents that were receiving less frequent parental care would abandon their magpie "parents" and join with other cuckoo fledglings that had been raised in non-mixed broods where they could be provisioned until independence (Roldán and Soler 2011). In this situation, the cuckoo fledgling's new magpie hosts would indeed "adopt" the fledgling, suggesting that the presence of the hosts' own fledglings may serve as an indicator for the host to identify parasitic fledglings (Roldán and Soler 2011; Soler 2019). Through these examples, among some others, it is known that the coevolutionary arms race does continue to encourage different adaptations at the fledgling of the breeding cycle.

### Conclusion

From its origins to the diverse adaptations associated with maintaining it, our understanding of interspecific brood parasitism, along with the coevolutionary arms race between parasites and hosts that it elicits, is a complex and continually changing affair. While the majority of research on this topic has overwhelmingly focused on avian IBP, new discoveries in insects and fish are providing the framework for deeper experimental dives onto the more discrete adaptations and counter-adaptations within these taxa. And as more research into the specifics of IBP in insects and fish continue, the genetic tools and perspectives that have bolstered our research in avian IBP will hopefully be applied here, helping to answer questions on the taxonomy and distribution of IBP in these understudied taxa. In addition, developmental, genetic, and neuroendocrine approaches to IBP research across taxa are continuing to refine and expand our understanding of different aspects of the breeding system such as the cognition of egg rejection, transgenerational effects of parasitism, and so much more. As these approaches answer questions regarding aspects of IBP in which our knowledge is already established, they will likely create new methods, ideas, and questions that can only seek to better explain the complexities of this extraordinary breeding strategy among species.

## Interstimulus Interval (ISI)

Chana K. Akins  
Department of Psychology,  
University of Kentucky, Lexington, KY, USA

In Pavlovian conditioning, the interstimulus interval (ISI) is defined as the time between the onset of a conditioned stimulus (CS) and the onset

of an unconditioned stimulus (UCS or US). It is therefore often referred to as the CS-US interval. Traditionally, investigators have viewed the ISI as determining whether or not learning will occur. The focus has been on identifying the interval that provides the best evidence of learning and identifying the limits of the ISI that will permit learning. The typical finding is that the shorter the ISI, the greater the likelihood of conditioned responding and/or the greater the conditioned response. For example, Schneiderman and Gormezano (1964) found that for conditioning of the nictitating membrane (secondary eyelid) of rabbits, a 250-ms ISI resulted in nearly 100% conditioned responding in 350 trials. In contrast, with a 4,000-ms ISI, conditioned responding did not increase much beyond 25% in 560 trials. Subsequently, the optimal ISI for nictitating membrane conditioning was found to be between 200 and 400 ms (Smith et al. 1969; but see also Levinthal et al. 1985).

There are two types of Pavlovian conditioning procedures that may influence the timing between the CS and the US (Domjan 2015): (1) delayed conditioning which occurs when the CS starts before the US and continues during the US or ends when the US begins and (2) trace conditioning which is similar to delayed conditioning in that the CS starts before the US but the US is not presented until some time after the CS has ended. Therefore, the latter has a gap in time between the CS and US. In general, though with some exceptions, stronger conditioning occurs with delayed rather than trace conditioning.

Substantial levels of conditioned responding have been observed with relatively long delays between the onset of the CS and the onset of the US in other conditioning preparations, such as taste aversion learning (e.g., Garcia et al. 1966). Taste learning occurs when a novel-flavored food or liquid (CS) is ingested and results in some form of illness and/or aversive outcome, the US (Reilly and Schachtman 2009). If the illness is delayed for several hours (a long ISI), a taste aversion may still occur (Garcia et al. 1966). However, even in this preparation, the general finding has been that acquisition is inversely related to the length of the ISI.

More recently, evidence has indicated that the length of the ISI also determines *what* subjects learn

rather than whether or not they learn. For example, Holland (1980) tested the effects of the interval between the onset of visual and auditory CSs and a food US in rats. The results showed that short-duration (1, 5, and 10 s) auditory CSs evoked high frequencies of startle and head jerk responses, while long-interval (30 and 60 s) auditory CSs evoked less startle and head jerk movements and more magazine-directed conditioned responses. Thus, auditory and visual CSs paired with food evoked considerably different topographies of conditioned behavior, and the nature of these differences depended on the length of the ISI.

More recent research with Japanese quail and the sexual behavior system has provided additional evidence for changes in the response topography as a function of the ISI. Male Japanese quail served as subjects, and access to a sexually receptive female served as the US. Previous studies have shown that with a spatially localized CS (i.e., a wooden block), subjects learn to approach and increase their time near the CS as sexual conditioning proceeds (Domjan and Hall 1986). Initial studies using traditional measures of approach to the CS (time spent close to the CS) suggested that learning was inversely related to the length of the ISI and occurred only if the US was presented within 10 min of the start of the CS. However, more extensive observations indicated that increases in the length of the ISI changed the nature of the conditioned response. Approach behavior was evident with intervals as short as 1 min, but increased locomotor activity (pacing behavior over a wide spatial area) occurred when the interval was as long as 20 min. (Akins et al. 1994) Therefore, using different behavioral measures, learning was obtained with ISIs as long as 20 min. In this study, both approach and locomotor activity were conditioned responses because they were not evident in any of the control groups.

These findings are consistent with the behavioral systems view of learning proposed by Timberlake and Lucas (1989). According to this model, presentations of a US in a conditioning procedure activate the behavior system relevant to that US. Behavior systems are assumed to consist of a series of modules organized in a temporal-

spatial sequence. Thus, for example, presentations of small portions of food to hungry animals are assumed to activate the feeding system. The feeding system is organized in a temporal-spatial sequence, starting with general search behavior (controlled by contextual cues). Once a potential source of food has been located, a focal search module is activated, which results in behavior limited to a smaller area in which the food is presumably located. Once the food has been located, food handling and consummatory response modules are activated. According to this behavior systems view, Pavlovian conditioning results in integration of the CS into the behavior system activated by the US. The conditioned behavior that comes to be elicited by the CS depends on which module is activated at the time of the CS presentation and that in turn depends to a large extent on when the CS is presented relative to the presentation of food, the interstimulus interval. Long ISIs are assumed to result in the conditioning of general and localized search responses. By contrast, short ISIs are assumed to result in the conditioning of food handling and consummatory responses. Thus, the nature of the conditioned behavior is assumed to vary as a function of the ISI.

## Definition

Interval timing refers to perception and behavioral control with respect to time in the seconds to minutes range.

## Introduction

Adapting behavior to the temporal relationships that occur in the environment is critical for survival and requires both perception and behavioral control with respect to time. The perception of time without an external aid, such as a clock, is a capacity that is so inherent that it is often overlooked. We can easily conclude that a stoplight is broken because we sense that we have been sitting at the light for longer than is typical. But how is this temporal sense and behavioral control manifest? Modalities such as vision, audition, and olfaction are processed through dedicated sensory structures that are impacted by different forms of energy, in the form of light, sound waves, or volatile particles to influence perception. In contrast, time perception does not result from measuring change in one specific form of external energy, but instead appears to result from one or more neural systems processing their own dynamics (at least under conditions in which other sensory signals are not changing). Indeed, one can imagine being blind, deaf, or anosmic as a result of disruption of specialized sensory receptors, but it is nearly impossible to imagine existing without sensitivity to the passage of time.

## Temporal Ranges

Sensitivity to time is commonly broken down into three primary categories as a function of their duration, and these systems have different neural underpinnings: circadian, interval, and millisecond timing. In descending order of duration, circadian timing evolved with respect to the 24-h solar period. Circadian rhythms primarily regulate sleep and motor activity, although a range of physiological functions demonstrate a 24-h periodicity. The circadian system, heavily dependent

on the suprachiasmatic nucleus of the hypothalamus, is very precise (e.g., the standard deviation in wheel running activity in rodents is less than 2% of the 24-h period – Herzog et al. 2004), but pays for this precision with inflexibility. It is limited to timing intervals close to 24 h, and it is slow to reset when the light cycle abruptly shifts (e.g., we get jet lag). Interval timing allows temporal perception and control in the seconds to minutes range, although sensitivity to durations that are several hours long has also been deemed to utilize interval timing processes. Besides allowing temporally specific expectations, interval timing contributes to optimal foraging (Kacelnik and Brunner 2002) and associative learning (Balsam et al. 2006). Perception of intervals in the seconds to minutes range lacks the precision of the circadian system, with variability in temporal production in rodents on the order of 25% of the interval being timed (Church et al. 1994). However, the interval timing system appears to be equally sensitive to all durations in its range and is able to begin timing a new interval without waiting for a previous interval to elapse. Multiple durations can even be timed concurrently. While the neural structures underlying interval timing remain highly debated, this capacity does not require the suprachiasmatic nucleus (Lewis et al. 2003). Lastly millisecond timing systems allow detection and control of behavior of very short intervals. For example, fine motor control, such as used for speaking and its corresponding auditory perception, relies on millisecond timing mechanisms. Such fine temporal processing appears to depend on computational processes directly tied to anatomical features or synaptic dynamics (Buonomano and Merzenich 1995). For example, delay lines, allowing the speed of action potential transmission to mediate the interval, are a basic mechanism in the detection of location of an auditory signal by computing the difference in a sound's arrival time at the ears.

## Timing Tasks and Properties

Interval timing has been demonstrated across a wide range of species. While verbal estimation

and production procedures have been used in human research (e.g., “How long did that interval last?”; “Please indicate when 15s has elapsed.”), the potential for between-subject variability in mapping verbal labels to intervals may result in difficulties in interpreting results from these approaches. As such, the use of reproduction and discrimination procedures, which can be used similarly for both verbal and nonverbal animals, is preferred to assay the degree to which an organism is perceiving and utilizing temporally specific information. A commonly used reproduction task is the peak-interval procedure. In this task, subjects are trained on a discrete trial, fixed-interval schedule, in which the first operant response (e.g., a lever press), following the passage of a criterion duration from the onset of a signal, is reinforced. For example, a hungry rat might receive a food pellet for making a lever press after 10 s has elapsed since onset of a tone. Upon reinforcement, the signal terminates and an intertrial interval presents an opportunity for the food to be consumed. Lever presses prior to the criterion interval, and lever presses emitted in the absence of the signal are recorded, but there is no programmed consequence to their occurrence. After sufficient training, subjects respond selectively during the signal and differentially as a function of time since signal

onset. Plotting the average rate of lever pressing as a function of time since signal onset reveals that responding occurs at a low rate early in the interval and then increases in a nonlinear manner (i.e., a scallop pattern), reaching a maximal rate around the time of the fixed-interval duration. As an increasing response rate function might result from a nontemporal rule, “increase rate if prior response wasn’t reinforced,” non-reinforced probe trials lasting several times the fixed interval are presented on a subset of trials (e.g., 25% of trials) to ascertain the temporal specificity of responding. On these probe trials, average responding first increases as in a fixed-interval trial, but then following the criterion duration, response rate decreases, resulting in a roughly normal-shaped response function centered around the fixed-interval duration. The time of maximal responding, the peak time, is treated as the subject’s estimate of the time of reinforcement. A representative example of the average peak function from a single rat trained on this procedure is shown in Fig. 1.

As mentioned above, the interval timing system has considerable flexibility, enabling timing of multiple intervals. The data shown in the left panel of Fig. 1 came from a rat that was trained that one cue (i.e., a tone) indicated that food might

**Interval Timing, Fig. 1** Average response rate functions from a single rat trained in the peak-interval procedure. In this procedure, a food pellet could be earned for the first response made 10 s after onset of a tone or 20 s after onset of a light. Responses prior to these intervals had no programmed consequence. Data displayed are from non-

reinforced probe trials that lasted at least 60 s. The left panel shows the raw response rate in real time, while the right panel plots these same functions as a proportion of elapsed time and normalized by maximal rate, thereby showing the scalar property (Unpublished data by McGovern and Matell)

be available after 10 s, whereas a different cue (i.e., a light) indicated that food might be available after 20 s. As can be seen, the peak time of responding for each cue matches the fixed interval associated with the cue, a property referred to as mean accuracy (Wearden and McShane 1988). Several other important properties of interval timing behavior can be seen in this figure. Peak spread (i.e., the standard deviation of the response function or the width at half maximal responding) is used as a measure of the precision or confidence of an organism's temporal estimates. Importantly, peak spread is directly proportional to the duration being timed, a relation known as the scalar property (Gibbon 1977). In other words, the entire response function scales or stretches to the interval being timed. The scalar property is frequently demonstrated by normalizing each response function by its maximal rate (i.e., its peak rate) and then plotting them as a function of the proportion of the fixed interval being timed. When this is done, the response functions for the two durations superimpose (shown in the right panel of Fig. 1). This relation can also be seen by computing the coefficient of variation (i.e., the peak spread/peak time), which will be constant for different durations if the scalar property holds. The scalar property is Weber's law for perceptual change applied to time. The third commonly seen property is that the peak rate is higher for shorter durations than for longer durations when trained with equivalent probabilities and amounts of reinforcement. As peak rate is viewed as an indicator of motivation related to expected reward value, the lower peak rate for the longer duration indicates that organisms discount the value of signaled reward as a function of the wait time. The steepness of this delay discounting function has been linked to impulsivity, and it is typically measured by identifying the duration at which subjects are equivalently likely to choose between an immediate small reward and a delayed larger reward.

Finally, it should be noted that the smooth peak functions shown in Fig. 1 are an artifact of averaging across trials. On an individual trial, responding is well characterized by a two-state, step-shaped pattern of responding in which the animal abruptly switches from responding at a

low rate to responding at a high rate prior to the fixed interval (i.e., the start time) and then abruptly switches back to a low rate after the interval has passed (i.e., the stop time) (Church et al. 1994). Because the time at which these abrupt response rate transitions vary from trial to trial, the step function is smeared, resulting in the smooth peak function. Single-trial analyses that identify the start time, stop time, spread, and midpoint of responding on individual trials allow for a more complete assessment of the processes generating temporal control. For example, the decision to initiate responding appears to be independent of the decision to terminate responding (Balci et al. 2009).

The peak-interval procedure measures prospective timing, which means that the animal is actively withholding responding until it deems sufficient time has elapsed that responding will be reinforced. This differs from retrospective timing, which occurs after the stimulus to be timed has been presented and the animal has to make a judgment concerning how much time elapsed before the termination of the stimulus. The temporal bisection task is used to demonstrate these posttrial temporal judgments. In this task, a stimulus is presented for either a short (e.g., 2 s) or a long (e.g., 8 s) duration, after which an option to respond on two different response manipulanda is provided (e.g., left and right levers are extended). The subject is reinforced when they respond on the manipulandum corresponding to the presented duration (e.g., if the stimulus was presented for 2 s, a left lever response is correct, and vice-versa). After duration discrimination reaches high levels of accuracy, intermediate durations are then presented, and the subject classifies each duration as "short-like" or "long-like" by responding on the corresponding lever. Plotting the probability of a long response as a function of presented duration is well described by a sigmoidal, or s-shaped, function. The point of subjective equality (PSE), the duration at which subjects are equally likely to classify an interval as short-like versus long-like, typically falls around the geometric mean of the anchor durations (e.g., 4 s for durations of 2 s and 8 s), although it sometimes falls closer to the arithmetic mean (i.e., 5 s for

durations of 2 s and 8 s). Bisection at the geometric mean has been interpreted as indicating that responding in this task is based on ratio, rather than absolute, similarity (i.e., ratio:  $2/4 = 4/8$ ; absolute  $5-2 = 8-5$ ). However, bisection at the geometric mean would occur with an absolute rule if temporal perception were based on a logarithmically growing percept, rather than a linear percept. Besides the PSE, one half of the difference in the durations for which the subject classifies an interval as long-like 25% of the time, versus 75% of the time, is referred to as the difference limen and, like peak spread in the peak procedure, reflects temporal precision. The scalar property is, of course, evident in this procedure as well, as computation of the Weber fraction (i.e., the difference limen/PSE) will be constant for different anchor durations. Some caution should be used when interpreting results from this task as indicating retrospective temporal assessment. When the response manipulanda are spatially oriented, rats and pigeons will show prospective-like timing behaviors, such that they will position themselves around the location of the short-associated manipulandum early in the trial and then move and position themselves around the long-associated manipulandum late in the trial. To minimize such mediating behavioral strategies, researchers have used different visual signals to indicate the short and long response and randomly varied their spatial position across trials (Machado and Keen 1999).

## Psychological Processes

While they differ in their mechanisms, all timing models can be conceived of in terms of an information processing structure that incorporates a clock process, a memory process, and a decision process. The clock process is instantiated by the generation of physiological signals that vary as a function of time, thereby creating a presumably isochronic relationship (i.e., a one-to-one mapping of brain states to elapsed time). The memory process stores a representation of the brain state associated with a particular biologically relevant interval (e.g., at the time of reinforcement) in

either short-term or long-term memory. The decision process compares the current percept (i.e., the evolving brain state) with the temporal memory or memories, and a response or choice is based on the similarity between the two.

To probe the mechanisms of timing, a common approach is to perturb the organism in some manner (either behaviorally or physiologically) and examine how temporal control is impacted. For example, the systemic administration of psychostimulants, such as methamphetamine, prior to a testing session in the peak procedure will cause the entire response function to immediately shift earlier in time (Meck 1996). These shifts are proportional to the duration being timed and, with continued training under the influence of the drug, will disappear (i.e., peak time will again be veridical). If drug administration is then discontinued, the response function will immediately shift right (i.e., later in time), again in a proportional manner, and will renormalize with continued training off the drug. Together, these immediate, proportional, and normalizing shifts are consistent with a change in the speed of an internal clock process and indicate that dopaminergic transmission plays a central role in modulating temporal perception and control. Besides altering the clock process, temporal accuracy (i.e., peak time) can be impacted by alterations of temporal memory processes, for example, through the administration of cholinergic drugs (Meck 1996) or through forced ambiguity of the appropriate temporal expectation (Swanton et al. 2009). Altering the latency to activate timing processes can also impact peak time. This effect, often attributed to attention, would result in an absolute, rather than a proportional, shift. Other manipulations, such as providing alternative targets for behavior, can alter temporal precision (i.e., peak spread), suggesting an impact on decision processes. However, an increase or decrease in variability in any of the central processes (clock, memory, or decision) will lead to changes in peak spread. The use of single-trial analyses can help dissociate the process alteration that gave rise to the change in peak spread. For example, if the spread of the high response state becomes broader, without an increase in variability of the start and stop times,

one can infer that the required similarity in the decision stage between the current percept and temporal memory has been relaxed.

## Interval Timing Models

Models of timing can be placed into three classes based on their mechanisms for the clock process: a pacemaker-accumulator mechanism, an array of temporal elements, and network state changes. Pacemaker-accumulator models consist of a pacemaker, which runs continuously, typically emitting pulses with Poisson variability (i.e., the time between pulses is exponentially distributed, with no relationship between one inter-pulse interval and the next). Upon onset of a signal to be timed, these emitted pulses are accumulated, thereby providing a signal that grows in a monotonic manner as a function of time. Within this class of models, scalar expectancy theory (Gibbon 1977) proposes that the pacemaker runs at a constant rate irrespective of duration being timed, and the value of the accumulator grows linearly as time elapses. One critical weakness of this model is the issue of instantiating such an unbounded accumulation process with neural architectures. In contrast, the behavioral theory of timing, its learning to time variant, and a drift diffusion-based model of timing (Simen et al. 2013) all propose that the rate of the pacemaker is inversely proportional to the delay to reinforcement. As a result, accumulation always occurs to a fixed bound, irrespective of the interval. As a model in the behaviorist tradition, the behavioral theory of timing does not utilize a cognitively accessible accumulation process per se, but instead deems the sequence of the animal's behavioral states to reflect elapsed time. Models that utilize temporal elements propose that different neurons or neural circuits operate with different time courses spanning the interval timing range, and by selectively strengthening and weakening the influence of these different elements, behavioral expression can be matched to the interval to be timed. Examples of models that utilize this approach are the spectral timing model (Grossberg and Schmajuk 1989) and the multiple oscillator connectionist model

(Church and Broadbent 1991). Finally, network state models propose short-time scale neural processes continuously interact, resulting in the evolution of a network state that varies with time (Buonomano and Merzenich 1995; Matell and Meck 2004). In contrast to the other classes of models, it is not clear that different network states can be viewed as evolving in a monotonic manner (e.g., activity becoming more/less complex or spreading/shrinking across the brain as durations increase), and thus it is difficult to evaluate whether the corresponding temporal memories (i.e., network states) can be acted upon via arithmetic operations. Such arithmetic operations are evidenced by findings that animals can combine the durations of independently trained cues to form a temporal map of events (Arcediano et al. 2003), that the number of trials to conditioned responding relates to the ratio of intervals between conditioned and unconditioned stimuli (Gibbon and Balsam 1981), and that rats respond in a scalar manner at an intermediate duration when presented with a compound of different modality cues that have been associated with different durations (Swanton et al. 2009).

## Neural Mechanisms

Given the multitude of models of timing, it should come as no surprise that the neural processes subserving the perception and behavioral control with respect to time remain unclear. Indeed, a long-standing, central question in the field (Roberts 1982) is whether time is processed by a network of dedicated neural structures or whether temporal processing is distributed, such that most or all neural structures process time as a central aspect of their activity. Support for the dedicated processing notion comes from findings that lesions to certain brain structures like the striatum (Meck 2006) severely disrupt the temporal control of behavior and from electrophysiological (Emmons et al. 2017; Mello et al. 2015) and functional imaging studies (Coull and Nobre 1998; Rao et al. 1997; Wiener et al. 2010) showing activation of specific neural structures within the frontal and parietal cortices and the basal

ganglia and cerebellum. Furthermore, temporal interactions across modalities (Roberts 1982; Swanton et al. 2009) and behavioral systems (Delamater and Holland 2008) suggest a common site at which such interactions could occur. On the other hand, to identify causal relations between the innumerable environmental events that come and go in time, one must keep track of the temporal relations between these events, which, given the multiplicative combination in possible relations, results in a computational explosion. Dealing with such a vast number of possible temporal relations may not be feasible by a dedicated neural framework (Ivry and Schlerf 2008). Indeed, temporally specific signals have been seen in areas such as the primary visual cortex (Shuler and Bear 2006) and the amygdala (Dallérac et al. 2017), and even in organotypic cultures (Johnson et al. 2010) suggesting that temporal information may be represented throughout the brain. Similarly, the fact that interval timing behavior has been seen across species, ranging from humans to rodents, birds to fish, and even invertebrates, suggests that timing does not rely on specific neuronal structures or cell populations.

## Conclusion

In summary, the perception of time in the range of seconds to minutes is a critical facility allowing a broad range of species the ability to organize their behavior with regard to the dynamics of the world. While there is agreement regarding many of the psychophysical features of interval timing, identifying the psychological and neural mechanisms of this capacity requires on going work.

## Intervening Variables

Heidi L. Shaw

Yakima Valley College, Yakima, WA, USA

## Definition

An *intervening variable* is an abstract scientific concept that scientists invoke to label or summarize relationships between independent and dependent variables across a variety of circumstances. Commonly cited examples of intervening variables include gravity, thirst, learning, and intelligence.

## Introduction

During his presidential address to the American Psychological Association in 1937, Edward C. Tolman used the term *intervening variable* in his comments regarding theories and facts:

But what is a theory? According to Professor Hull, a theory is a set of definitions and postulates proposed by the theorist (on the basis presumably of some

already found facts) from which other empirically testable facts, or as he calls them, theorems, can be logically deduced. These deduced theorems will be new empirical relationships which the theorist—or more often, his research assistants—can, then and there, be set to look for.

For my own nefarious purposes, however, I wish to phrase this matter of the relationship of a theory to the empirical facts out of which it arises and to which it leads in somewhat other terms. A theory, as I shall conceive it, is a set of “intervening variables.” These to-be-inserted intervening variables are “constructs” which we, the theorists, evolve as a useful way of breaking down into more manageable form the original complete  $f_1$  function.

Tolman’s  $f_1$  function referred to the causal relationship or the description of the dependence of the behavior (i.e., dependent variable) on the preceding stimulus (i.e., independent variable). To illustrate, consider Tolman’s hypothetical learning experiment involving the intervening variable of “hunger” (Tolman used the term “demand”). In this experiment, the researcher manipulates the hours since rats last ate (12-, 24-, 36-, 48-, 60-, 72-h prior) and measures the tendency of the rats to turn down the alley with the food. The independent variable of time since last meal corresponds to level of hunger. The more time that passes since an organism last ate, the hungrier the organism becomes. Presumably rats who last ate 72 h before entering the maze would be hungrier than rats who had eaten 24 h before entering. Resulting differences between groups of rats in the dependent variable of turning down the alley with the food would by definition directly mirror the variations in level of hunger. Rats who quickly learned to find the food would be the hungrier rats. The concept of hunger describes the causal relationship between time since last meal and speed of learning to find food.

Around the time, Tolman gave this address, Hull was using terms including “hypothetical construct,” “symbolic construct,” and “intervening variable” more or less interchangeably. Tolman’s 1937 address and 1938 paper sparked extensive discussion and debate among psychologists, particularly among learning theorists, about the extent to which the concepts differed, and to what extent it even mattered. MacCorquodale and Meehl (1948) are among those who

contributed to disentangling *hypothetical constructs*, which presume the existence of a tangible entity, process, or event, from *intervening variables*, which make no such presumption. Clearly distinguishing between these two concepts is crucial to understanding intervening variables.

## Distinguishing Intervening Variables from Other Unobservable Concepts

Hypothetical constructs are salient in a number of settings. Scientists postulate hypothetical constructs at a point in time when tangible entities are as yet undiscovered and unobservable. Gregor Mendel, for example, deduced from his records that pea plants must produce different variations of egg and pollen cells. Though Mendel himself was unable to measure differences in these cells, his hypothesized *Erbfaktoren* (heritable factors) were later confirmed by direct measurement with advanced technology. Of course, now *DNA* and *genes* commonly appear in science curricula as tangible things, but at the time Mendel was conducting his research, Mendel’s heritable factor was a hypothetical construct.

Researchers must address hypothetical constructs when designing and drawing conclusions from studies. In an experiment, for example, a researcher manipulates an independent variable, measures a dependent variable, and controls as many extraneous variables as is practical in an effort to rule out the effects of other likely causal variables. The researcher must also randomly assign subjects to experimental conditions in order to control for variables that may influence the outcome, but which may be impractical or impossible to control or which may indeed be unknown. These variables are presumably very real and as such are hypothetical constructs. Similarly, when drawing conclusions from correlational and quasi-experimental designs, researchers should be careful to avoid inferring cause because of possible “third variables.” While a study may show that a relationship exists between variables, a researcher cannot conclude a causal relationship between the two variables because of the many other variables, known or

otherwise, that could account for the observed relationship. As in experiments, these variables are presumably real, but unknown.

In MacCorquodale and Meehl's analysis, an *intervening variable* differs from a hypothetical construct in that an intervening variable involves no hypothesis of a tangible entity, process, or event. Intervening variables are unobservable concepts that are inferred from the manner in which the independent and dependent variables are operationally defined and are employed as logical links between independent and dependent variables (Bugelski 1956; Goodwin 2015). Though *intervening variables* are inferred to be causal, they are in fact labels for relationships between measurable variables rather than tangible entities in their own right. Gardner and Gardner (1998) offer a hypothetical experiment in classical conditioning to illustrate this point. Suppose that on each trial the experimenter flashed a light, then gave the dog some food. The experimenter measured the number of drops of saliva collected in a test tube on each trial after flashing the light, but before presenting the food. A graph would then show the learning curve, that is, how the number of drops of saliva increased from trial to trial.

Where is the learning in this curve? Obviously, there is no learning in the saliva in the test tube. Equally obviously, there is no learning in the light or in the food. A single trial can never yield any evidence of learning. The only evidence of learning is in the relationship between trials. We can see and measure the saliva, and we can see and measure the light and the food and the time between them, but we can only infer the relationship from trial to trial by looking at the record and making inferences. (Gardner and Gardner 1998, p. 6)

Intervening variables include mathematical constants, such as the acceleration of a falling body, as well as the myriad internal states or processes within organisms that fall under the umbrella of *psychological constructs* or *cognition*, such as learning, hunger, fear, intelligence, motivation, self-esteem, attachment, memory, consciousness, introversion, perception, and attention.

In order to advance an intervening variable as a causal factor, a researcher must rule out

competing hypotheses. Halliday (1983) illustrates this point with the example of forgetting:

We may say a person has forgotten a behavior if the behavior doesn't occur as often. Forgetting would be an intervening variable. We can't measure it directly, but it affects behavioral output. In order to say that "forgetting" has occurred, we have to rule out other possible explanations for why the behavior may not be exhibited. We would have to rule out maturation, for example. If the behavior disappeared because of normal biological development, we couldn't say that the behavior had been forgotten. If a response to a stimulus declines over time after repeated exposure, we might say that we forgot the response, but habituation would account for that. We would have to rule out fatigue as well. (p. 105)

A researcher would also have to rule out the use of drugs or intoxicants, level of sleep deprivation, state of health, etc. The fact that learned behavior fails when the person is intoxicated, tired or sick does not mean that forgetting has occurred. When the person returns to a normal state, performance may return to normal levels even without additional training (Hilgard and Bower 1966).

## Conclusion

MacCorquodale and Meehl (1948) suggest that intervening variables are useful for their convenience. Their summarizing nature allows scientists to develop more coherent and parsimonious theories (Hilgard 1956). Though intervening variables have no tangible substance, researchers can accurately compare findings across studies when intervening variables have unequivocal and measurable operational definitions. And intervening variables allow for ease of discussion. It is easier to say, "This child has an IQ of 100," than it is to say, "This child behaves as intelligently on this sample of test problems as the average child of his age" (Chaplin and Krawiec 1960). As Halliday (1983) cautions, however, "when an intervening variable is invoked, we should not believe that anything has been explained; all that has been done is that some phenomenon that requires explanation has been identified" (p. 105).

Despite MacCorquodale and Meehl's efforts to illustrate the difference between intervening

variables and hypothetical constructs, the term *intervening variable* continues to appear in contexts where using *hypothetical construct* would be more precise.

## Introduction

The ability of an organism to integrate sensorimotor functions and visuospatial processing confers major survivability advantages, because they allow organisms to adjust their behavior in response to the environment. The intraparietal sulcus is the location for many of these functions in humans. The primary somatosensory area is located posterior to the central sulcus and is guarded more posteriorly by a postcentral sulcus. Dorsal to postcentral sulcus, the intraparietal sulcus (IPS) divides the parietal lobe into superior and inferior parietal lobules consisting of areas 5 and 7, which are considered to be the sensory

association areas (Fig. 1). Turner in 1866 described the intraparietal sulcus to be located within the parietal lobe and having an ascending and horizontal course. He also mentioned that IPS could be recognized from the 6th month of intra-uterine life (Turner 1866). Cunningham in 1892 studied the configuration of intraparietal sulcus and its relation to that of the postcentral sulcus and classified it into five types. There is also a short sulcus called the anterior intermediate parietal sulcus of Jensen described on the inferior bank of the IPS which descends across the inferior parietal lobule and separates the supramarginal gyrus from the angular gyrus (Cunningham 1892). The type where intraparietal sulcus was fused with the superior segment and the inferior segment of the central sulcus was found to be the most common variety (Ono et al. 1990).

Toward the end of the twentieth century, many researchers extensively studied the cortical area within the depth of intraparietal sulcus and divided it into different areas (Choi et al. 2006). These areas of the cortex of the IPS are implicated in various functions and sensorimotor integration, saccadic eye movements, visuospatial information processing, and hand movements including grasping (Shikata et al. 2008).

But the consensus about the precise role of these areas responsible for such functions is lacking.

**Intraparietal Sulcus, Fig. 1** Schematic diagram showing the location of various areas related to the intraparietal sulcus (IPS). CS, central sulcus; PCS, postcentral sulcus; SFG, superior frontal gyrus; MFG, middle frontal gyrus; IFG, inferior frontal gyrus; SMG, supramarginal gyrus; AG, angular gyrus

## Intraparietal Sulcus in Macaques

The cortical gray matter in the region of IPS in macaques has been divided into a number of smaller functional areas such as anterior intraparietal area (AIP) and is concerned with planning and organizing grasping movement of the hands. The lateral intraparietal area (LIP) is associated with the planning of eye movement (Andersen and Buneo 2002) and also supplies the visual information about shape and position of objects to the AIP (Janssen et al. 2008).

The ventral intraparietal area (VIP) situated in the depth of the IPS is related to the response to the visual stimuli or light touch (Duhamel et al. 1998). The medial intraparietal (MIP) area and posterior intraparietal (PIP) area act altogether and function in the planning of reaching movements and also guide the course of movement to avoid errors and perform the smooth reach of the intended objects (Mulliken et al. 2008).

Finally, the caudal interparietal (CIP) area, on the caudal part of the lateral bank of the intraparietal sulcus, is involved mainly in the higher-order visual processing but not in the somatosensory processing, being a part of the parietal cortex (Fig. 2).

## Neurological Connection of Intraparietal Sulcus

The human intraparietal sulcus is divided into three areas, HIP1, HIP2, and HIP3, which resembles areas AIP, VIP, and MIP, respectively, in

**Intraparietal Sulcus, Fig. 2** Schematic representation of the different areas in the intraparietal sulcus. MIP, medial intraparietal area; PIP, posterior intraparietal area; VIP, ventral intraparietal area; LIP, lateral intraparietal area; AIP, anterior intraparietal area; CIP, caudal interparietal area

macaque monkeys (Scheperjans et al. 2008). hIP 1 and hIP 2 are situated in the anterior part of the intraparietal sulcus. hIP 1 is situated at the bottom of the intraparietal sulcus, and hIP 2 is situated alongside the lateral wall (Choi et al. 2006). These anterior regions of the IPS are chiefly connected by association fibers with the ventral premotor cortex and the middle frontal gyrus. hIP 1 is also connected to the insular region. hIP 1 region is involved in the grasping of the objects, manipulating of the objects, and processing of the three-dimensional object features, which are relevant for grasping (Fig. 3).

The hIP 2 region by virtue of its connectivity with the frontoparietal networks is important for transforming visuospatial information from hIP3. hIP 1 and hIP 2 together are involved in supporting more complex aspects of numerical and mathematical information processing. The hIP 3 is located in the medial wall of the IPS and connected with the extrastriate areas. It has a large number of fibers along the fronto-occipital fasciculus connecting to the fronto-occipital cortex. Because of this networking, hIP3 has a great role in modulating the visual information from the occipital cortex for further processing, i.e., visuo-spatial transformation. The combined action of these areas is essential for integration of the visual information with the spatial, motor, and somato-sensory information for graceful hand-eye coordination and movement through the environment (Schall et al. 1995).

## Functional Imaging for Intraparietal Sulcus

Functional neurophysiological studies done using the fMRI revealed the complexity of the areas in the intraparietal sulcus in macaques as well as in humans (Murata et al. 2000). Studies conducted on humans showed grasping areas in the depth of intraparietal sulcus. One of the studies illustrated that any vascular or traumatic lesion to the anterior part of the IPS results in impaired grasping behaviors, while similar lesions in the posterior part of the IPS have no effects on the grasp pattern of the subjects (Binkofski et al. 1999).

Observation showed that grasping abnormalities were present in the form of slower hand opening while reaching the objects, formation of larger gaps, or apertures between the thumb and other fingers as compared to the non-affected side of the same patient and also with age-matched controls.

Effects of grasping and manipulation of rectangular blocks showed the areas of activation in the lateral part of the IPS. Subsequently, studies were carried out to confirm the activation of the anterior part of the IPS during grasping and manipulation of objects (Frey et al. 2005).

## Clinical Correlates for Sulcus

Various neurological and visual disorders were correlated with the involvement of the

**Intraparietal Sulcus, Fig. 3** Briefing of functions of the various areas in the intraparietal sulcus

areas of intraparietal sulcus. The particular area in the intraparietal sulcus is concerned with the saccade generation but, due to the vascular or traumatic lesion to the area, may result into the increased saccadic latencies and reduced amplitude of contralateral directed reflexive saccades (Pierrot-Deseilligny et al. 1987) and memory-guided saccades (Muri et al. 2000).

Some authors also correlate the involvement of intraparietal sulcus in developmental difficulties in mathematics, also called as developmental dyscalculia (DD) (Molko et al. 2003). He carried out analysis of Turner syndrome (TS) patients with mathematical deficits and revealed abnormal structural organization of the right IPS. In a second study, Molko et al. (2004) supported this finding with voxel-based morphometry (VBM) evidence that TS subjects showed decreased gray matter volume in the left superior temporal sulcus and right IPS. A more recent VBM study revealed reduced gray matter volume in the right IPS in DD children relative to controls (Rotzer et al. 2008).

## Definition

Intra-sexual selection is part of sexual selection where members of the same sex (males) compete with each other to gain access to mate with females.

## Introduction

It is the rule of nature when multiple individuals eye on the same resource whether it is food, shelter, or mate; consequently, competition arises among them. In sexually reproducing animals, sexual selection operates in a similar manner like natural selection. If sexual selection results in direct combat between members of the same sex of a species, concerning the propagation of species, it is referred to as intra-sexual selection. The intra-sexual selection reflects the competition between members of the same species (specifically males) in order to gain opportunities to mate with the opposite sex. For example, the

males compete with each other for mating with females. Intra-sexual selection mainly occurs in a group of animal species where the female mainly involves in parental care and male likely to compete with each other for success in mating (Hall and Strickberger 2008). As a result of frequent competition, the individual with better adaption in combat strategies/traits has more chances to attract females. It is opposite of intersexual selection which is also known as a female choice, where female chooses the male based on certain characters/ornaments, e.g., a peacock's tail. Although the term inter/intra is rather capricious because competition for a mate must be within the members of the same species, the term inter/intra is mostly used for within two groups and between the same group, respectively.

Since the intra-sexual selection involves a rivalry between members of same species, the conflict can result into direct interactions causing severe fight, thus individual of a species are well adapted for intra-sexual competition mostly have developed better armaments or intra-sexually selected weapons (ISW) than their competitor.

The origin of intra-sexual selection concept came to existence in 1871 when Darwin described the sexual selection theory and how the evolution of many beautiful and sophisticated traits occurred in nature. According to Darwin, "Success of certain individuals of a species over others in relation to the propagation of species is the result of sexual selection."

In nature, the intra-sexual selection is more prominent, where males being polygynous mate with many females (Hall and Strickberger 2008). In such species, males generally have well-developed masculine traits or armaments in order to gain a mate. Due to selection pressure, these characters become inherited and lead to distinct sexual dimorphism (Weir 2013; Singh et al. 2019). For example, males are generally found to be larger in body size with respect to female body size (male elephant seals; *Mirounga leonina*), male dung beetles (*Onthophagus taurus*) have longer horns, similarly in melon flies (*Bactrocera cucurbitae*) the males and female show several dimorphic features, where male being shorter than female and structural variation

in wing morphology also present (Singh et al. 2019). The sexually dimorphic traits are generally under hormonal control.

**Armaments:** It has been found that intra-sexually selected weapons (ISW) are mostly found in the animals with bilateral symmetry. In a report by Rico-Guevara and Hurme (2019), they have reported that most of the ISW comes in pairs, located mostly near the head region, and are part of modified endo- or exoskeleton. These structures may excessively develop over generations due to selection pressure. In the terrestrial system, most of the modifications are observed in feeding parts and locomotory appendages. Some examples of ISW are longer horn in male dung beetles (*Onthophagus taurus*) which is modified chitinous exoskeleton. The development of a longer horn in dung beetle is dependent on the nutritional regime on which the insect has fed during development. Male bighorn sheep (*Ovis canadensis*), native to North America, have huge horn over their head which they use in headbutt during combat with other males, to gain excess to female. Intra-sexual conflict in Alaskan bull-moose males (*Alces alces gigas*) is so intense that sometimes both males die due to tangling of their horns. The male gorilla has well-developed musculature, fist, and canine which he uses in combat.

## Competition

Since competition is the main driving force for intra-sexual selection, it can be categorized into two groups. The first one is a case where the male, who reaches the female first, will be able to mate (scramble). The second is where two or more males compete over female and the winner will mate (contest). The first in the list of competition, i.e., scramble, which refers to race for getting female first. For example, in damselflies (order Odonata), the male with the help of its claspers grasps the head of the female as soon as she arrives. There is variation in the structure of the claspers from species to species. In fact, it is species characteristics to prevent interspecific mating. Scramble competition is also cited in the case of dung beetles and elephant seal (Moya-

Laraño et al. 2007). Here the small-sized males succeed over large males in getting female due to their fast and active movement, whereas large-sized elephant seal tends to win in contest, i.e., combat.

It must be considered that males with larger size are more successful over smaller sized but have reduced daily reproductive ability, whereas the smaller animals have high agility and more daily reproductive capability. Being intermediate in size is beneficial for animals to be reproductively more successful.

## Alternative Mating Strategies

From the above discussion, it could seem like smaller-sized male or males with inferior combat strategies or ISW would be at a disadvantage during contest competitions for mating. But it is not always true; in some species the inferior male has developed some alternative mating tactics for ensured reproductive success (Pagel 2002).

**Sneaking Strategy:** sometimes the smaller male waits for the opportunity when the dominant male gets engaged in combat with some other males or mating with another female; the smaller male sneaks in and copulates with the female. For example, in red deer (*Cervus elaphus*), the smaller males with inferior antlers instead being indulged in direct combat with superior males wait near a female deer until the large male gets engaged in a contest with another competitor; the inferior male then sneaks in and copulates with the female. This kind of strategies is also used by inferior males of elephant seals and cichlid (*Herichthys minckleyi*) (Cherfas 1977; Frankenhuis and Fraley 2017).

**Tunnel digging** by males of horned beetles (*Onthophagus acuminatus*). In horned beetles, the dominant males with long horn guard the female nest/tunnel and combat with other males trying to enter the tunnel. The subordinate male instead of direct encountering dominant male at the tunnel entrance digs a secondary tunnel to intercept the female tunnel (Pagel 2002).

**Early maturation** in coho salmon (*Oncorhynchus kisutch*) – coho salmon is an

anadromous fish of Salmonidae family. After embryonic development, the male and female spent 3 years in seawater before they return to freshwater for spawning. Some of the males leave the seawater at 2 years of age and are called as Jacks (smaller in size); other males who spent 3 years in seawater are larger and are known as Hooknoses (Oldfield et al. 2014).

## Sperm Competition

When a female has mated with one male, it is possible that another male can also fertilize her releasing its sperm in the female genital tract (Wigby and Chapman 2004). In hymenopterans, especially in honeybee (*Apis*) and many coleopterans, the queen female has the capability to mate with two or more drones and even store their sperms. Later the female on its will uses the sperm to fertilize her eggs. This process of sperm selection is often known as sperm discrimination. When virgin queen goes for a mating flight, she mates with up to seven to ten males. The male drone inserts its endophallus and releases sperm. After completion of mating, the drone pulls away, but a part of endophallus get ripped off and remain attached to the female's body. When another male mates with the same female, it has to first remove the existing endophallus of the previous male. This type of behavior in several insects leads to the basis of sperm competition, where the sperm of one male competes with the sperm of another male inside the female reproductive tract. To prevent this sperm competition, some species have developed certain strategies. The fundamental way is copulation guarding. The male guards the female prior to copulation until she gains sexual maturity and till the female laid her eggs or produce progeny (Wigby and Chapman 2004).

There are two specialized methods, which have been evolutionary curretted for sperm competition:

**Scrapers** – In some species, the males have modified body structure to remove the sperm of other males from the female reproductive tract, for example, dragonfly males (Langley 2016).

**Mating Plugs** – In some species, the males release certain chemicals or protein which makes the female incapable to receive sperm from other males. This method is also known as the copulation plug. Mating plug is generally gelatinous secretion released by males in the female reproductive tract. For example, mating plug in a female Richardson's ground squirrel (*Spermophilus richardsonii*) and *Bombus terrestris* (Baer et al. 2000; Wigby and Chapman 2004).

A third category which is reported in *Drosophila* is **sperm fertilization power**, where the males increase the fertilization capacity of their sperm resulting in more chance that their sperm will fertilize the female eggs. The content of male seminal fluids also contributes to dominating female fertility and sexual behavior.

## Consequences on Female Fitness

Intra-sexual competition between males can have both negative and positive effects on female fitness. As we have discussed above, the success of superior males in mating leads to the inheritance of its gene. But it is not always correct. In a population with a high density of males over female, a large number of males try to mate with female resulting in a negative impact on female reproductive organs. Even a higher rate of male-male competition could lead to the loss of superior male after some combat. High level of intra-sexual competition leads to a decrease in female investment toward mating and parental care (Weir 2013; Cayuela et al. 2016).

## Consequences on Male Fitness

Intra-sexual selection in the course of evolution leads to deposition of certain traits which result in prominent sexual dimorphism, and such traits become inheritable. Some of the examples are traits which are useful in mate search and dispersal of male (e.g., male wing morphology in dragonflies and damselflies); traits involved as ISW/armaments; and traits that enhance copulation capability and sperm competition which would have fair chance to be favored. Improvement of endurance is also an important

aspect which increases superior male mating ability (Rico-Guevara and Hurme 2019).

## Sexual Selection in Human Perspective

Scheyd (2018) described a lot about sexual selection in human perspective. In the human's case, sexual selection operates merely more or less in the same way as in the case of the whole animal kingdom. Huge reports are available on the psychology of human about sexual and romantic jealousy and partner selection. In humans, males are more prone to sexual infidelity, whereas females are prone to emotional infidelity. In simple words, males are suspicious, whereas females are emotional. Intra-sexual rivalry in the human case also results in a sort of aggressive remedy (Brase et al. 2004). Typically male-male rivalry relies on sort of physical violence mostly covert, whereas female-female rivalry mostly overt relies upon verbal aggression damaging reputation of rival (Hyde 1984; Werner and Crick 1999).

Sexual selection (both intra- and inter-sexual) plays a key role in our system too. Sexual dimorphism is key to sexual attraction in every dioecious system. Human males don't get involved in direct combat with another male to attract women; rather, they spent valuable time and resource in the gym for developing body musculature and make their physical appearance more prominent (Scheyd 2018). The same muscle system can be involved in combat tactics. Here the intra- and inter-sexual selection operates at the same time. Spending time in parlor and salon for their look is part of inter-sexual criteria. In nature, the strong musculature and smart look are related to sexual wellness, productivity, and superior future generation.

Human females, similar to human males, are also prone to sexual selection conflict at the same level. Fisher (2013) studied this aspect with a catalogue of behavioral characteristic, including some sort of aggression, like breaking confidences, criticizing others, clothing, appearance, personality, gossiping, and so on. In the case of same-sex rivalry, females are found to be superior to males (De Backer et al. 2007). All these

behavioral phenomena are intra-sexual competition for desirable mates. In simple words, all sorts of behavior correspond to female-female competition, with the sole purpose to be superior over others. In addition to this intra-sexual aggression, they also go for self-promotion and mate manipulation (Fisher and Cox 2010). In a study by Hill and Durante (2011), it has been found that when women were shown images of other beautiful women, they showed and increased behavior to enhance their own attractiveness.

## Conclusion

In the course of evolution, natural selection has governed the selection of certain individuals over others with respect to fitness. Sexual selection, on the other hand, shaped the sexual dimorphism and inheritance of those traits which results in better adaptability of future progeny, although exception does exist. Reproductive success is the primary way by which nature judges an organism's success over others. In either intra- or inter-sexual selection, the sole purpose is the selection of superior mate over others. Although the superior mate may have certain undesired genetic endowment, however, due to its selection as a potential mate, it is capable to inherit such traits to ensuing generations.

## Intromission

Andrew M. Holub and Todd K. Shackelford  
Department of Psychology, Oakland University,  
Rochester, MI, USA

## Synonyms

Coitus; Copulation; Sexual intercourse

## Definition

Intromission is a step of sexual reproduction that involves the insertion of a male intromittent organ into the cavity of a female reproductive organ to facilitate insemination and internal fertilization.

## Fertilization through Intromission

Because sexual reproduction necessitates the combination of gametes from two different individuals, a variety of modalities have evolved across taxa to achieve fertilization. Within the kingdom Animalia, sexual reproduction can be divided into categories according to where fertilization occurs: internal or external to the body. Among internal fertilizers, males of many taxa have evolved intromittent organs that are designed to deposit spermatozoa inside the female reproductive tract, although never directly on ova (see Eberhard 1985, 2010). There are notable exceptions of internal fertilization occurring without the use of intromission, most prominently among many avian and reptilian taxa, in which insemination occurs through transfer of male gametes to female reproductive tract across the cloacae in a process commonly called a “cloacal

kiss” (e.g., Morrison et al. 2018), which may mimic copulation. The majority of taxa of the order Urodela reproduce via indirect insemination, during which a male drops a spermatophore on an external surface and females may select to insert it through a cloacal opening (e.g., Houck and Arnold 2003). However, intromission is the most common means of fertilization among terrestrial animals (Austin 1984). Intromission is ubiquitous throughout the class Mammalia, although in at least one species (*Homo sapiens*) fertilization has been documented to occur unaided (i.e., without artificial intervention) without intromission (e.g., Achour et al. 2019), although such cases are rare. Intromission is typically reproductive in purpose, although non-reproductive sexual behaviors in general (to include intromission) are common especially among social taxa (e.g., Furuichi et al. 2014).

Males and females occupy distinct reproductive niches that result in sex-related differences in reproductive traits (see Eberhard 1985, 1996; Trivers 1972). Many of these adaptations are the result of sexually antagonistic selection or sexual conflict (Parker 2006; see Dougherty 2017). In short, sexual adaptations in one sex often facilitate the reproductive interests of individuals of that sex at the expense of the reproductive or survival interests of the individuals of the other sex (Lessells 2006; cf. Eberhard 2010). Thus, the behaviors and circumstances surrounding intromission vary widely across taxa, as do the morphologies of sexual organs (see Austin 1984; Eberhard 1985, 2010). For example, the hectocotylus of the class Cephalopoda is a limb that stores and delivers spermatophores to females by means of insertion (Laptikhovsky and Salman 2003). Similarly, Arachnida males use an appendage called a pedipalp, on which a spermatophore is typically deposited, stored, and eventually inserted into female reproductive organs (Michalik and Ramírez 2014). Pedipalps are not genitalia, but rather an intermediate organ for reproduction with other functions, such as sensation (Talarico et al. 2008). Female reproductive organs have likely evolved to alter the reproductive process, thus driving the evolution of

intromittent organs, although more research is needed on the morphological variability of female genital organs in order to better understand this copulatory coevolution (Brennan 2016).

## Synonyms

### Noncoding DNA

## Definition

Introns are noncoding regions of an RNA transcript, or the DNA encoding it, which are eliminated by splicing before translation.

## Introduction

In 1977, using the adenovirus model system, Philip A. Sharp and Richard J. Roberts independently discovered that genes could be discontinuous (Berget et al. 1977; Chow et al. 1977). Subsequent research in four different laboratories revealed that intervening noncoding sequences were also present in genes encoding different proteins in vertebrates such as the rabbit  $\beta$ -globin gene, the mouse  $\beta$ -globin gene, and the chicken ovalbumin gene. These noncoding intervening sequences were given the term introns by Walter Gilbert.

## Size of Introns

Noncoding intervening sequences are part of most eukaryotic genes. The frequency and size of introns vary largely. For example, the *Xenopus laevis* (African clawed frog) gene that encodes vitellogenin A2 is known to have 33 introns. The Ultrabithorax gene of *Drosophila* has an intron that is about 70,000 nucleotide pairs in length. The gene encoding for the  $\beta$  chain of hemoglobin has two introns – a long intervening sequence of 550 base pairs and a short one of 120 base pairs that split the  $\beta$ -globin gene into three coding sequences. Intron sequences constitute approximately 25% of the human genome, of which <0.01% of the introns are <20 bp in length and <10% of introns are more than 11,000 bp in length (Sakharkar et al. 2004) (Fig. 1).

## Types of Introns

Four classes of introns have been identified and studied in detail:

- (i) Introns of tRNA precursors – These introns are excised in two steps by endonucleolytic cleavage and ligation reactions catalyzed by splicing endonuclease and ligase. Studies on tRNA precursor splicing have been carried out in detail in the yeast *Saccharomyces*

**Intron, Fig. 1** Introns are noncoding sequences of nucleic acids that interrupt the coding sequences (i.e., exons) in a gene. An intron is excised from the primary RNA transcript by splicing and is a common feature of eukaryotic genes

*cerevisiae* model. In the first step, a nuclear membrane-bound splicing endonuclease makes two precise cuts at the ends of the intron. In the next step, a splicing ligase joins the two halves of tRNA to form the mature form of the tRNA molecule (Greer et al. 1983).

- (ii) Introns of nuclear pre-mRNA transcripts – Nuclear pre-mRNA introns, also known as spliceosomal introns, are characterized by specific intron sequences located at the boundaries between introns and exons (GU at 5' end of the intron and AG at 3' end of the intron). These introns also have a branch point site close to the 3' end of the intron with a highly conserved A residue followed by a polypyrimidine tract. These introns are excised by complex transesterification reactions in two steps by RNA/protein structures called spliceosomes. Spliceosomes are dynamic structures made

up of uridine-rich small nuclear RNAs (snRNAs) and protein complexes called small nuclear ribonucleoproteins (snRNPs). Through complex RNA-RNA, RNA-protein, and protein-protein interactions, the snRNPs mediate the splicing of introns in nuclear pre-mRNA (Watson et al. 2003).

- (iii) Group I introns – Group I introns share common folding pattern and are self-splicing introns, i.e., they catalyze their own excision from mRNA, rRNA, and tRNA precursors. In these introns the splicing reaction is initiated by guanosine or one of its 5'-phosphorylated forms (GMP, GDP, or GTP), which attacks the phosphorus atom at the 5' end of intron and forms a 3', 5'phosphodiester bond to the first nucleotide of the intron. The 5' exon, now having a free 3' hydroxyl group, then attacks the phosphorus atom at the 3' end of the intron resulting in ligation of the exons and excision of the intron (Cech

**Intron, Fig. 2** (continued)

1990). These introns are found in mRNA, tRNA, and rRNA in the mitochondria and chloroplasts. They are also present in bacteriophages, eubacterial genomes, and nuclear genomes of non-vertebrates.

- (iv) Group II introns – Group II introns are also self-splicing and catalyze their own excision from mRNA, rRNA, and tRNA precursors. The splicing of these introns involves two transesterification reactions similar to that of nuclear pre-mRNA introns. These introns are present in the mitochondria and chloroplasts. They are also found in cyanobacteria and proteobacteria (Fig. 2).

## Conclusion

Regarding the origin of introns, there are two opposing views. According to the “introns early model,” protein-coding genes were interrupted by numerous introns even in the early stages of evolution. The absence of spliceosomal introns in prokaryotes is considered to be a result of “genome streamlining.” According to the “introns late” hypothesis, spliceosomal introns emerged late in evolution in eukaryotes and got inserted into protein-coding genes continuously throughout the evolution of eukaryotes. Irrespective of which view is correct, presence of introns and the need to remove them allows for alternative splicing. Alternative splicing is the molecular mechanism that can generate multiple protein products from a single

gene in a eukaryotic cell, thereby enhancing the protein repertoire and genetic diversity.

**Intron, Fig. 2** Steps in the splicing mechanisms of the four classes of introns. (i) **Splicing of tRNA precursors:** many precursor tRNAs contain introns of 10–20 nucleotides in length. These introns are removed by a series of enzymatic reactions (which uses endonuclease, kinase, and ligase). The endonuclease generates a 2',3' cyclic phosphodiester which is opened by a phosphodiesterase to provide a 3'-OH for the ligase reaction. Every splicing episode uses 2 ATP molecules. (ii) **Splicing of introns in pre-mRNAs:** Splicing is initiated at the “branch” point where 2'-OH of an A forms a phosphoester with the first G of the intron. Splicing occurs through transesterifications. The 3'-OH of the upstream exon reacts

with first nucleotide of the downstream exon, so that the two exons join through phosphoester transfer mechanism. snRNPs (U1, U2, etc.) form functional spliceosome on pre-mRNA and catalyze the splicing reaction. (iii) **Group I introns splicing:** the 5' phosphate of the first intronic nucleotide get connected to the 3'-OH of the G nucleotide with the 3'-OH of the last nucleotide of the upstream exon available and join the 5' phosphate of the first nucleotide of the next exon. This excises the intron and the two exons join by phosphoester transfers. (iv) **Group II introns splicing:** The mechanism of group II introns splicing is similar to that of nuclear pre-mRNA splicing. These splicings can also be reversible like in the group I introns.

## Definition

Inversions are the chromosome structural aberrations brought about when a segment of a gene on chromosome breaks, and turned 180 degrees and rejoin to the remaining chromosome.

## Introduction

Figure 1 is showing a heterozygous para-centric inversion in the third chromosome of

**Inversion Effects, Fig. 1** Photomicrograph of para-centric heterozygous inversion present in third chromosome of *D. bipectinata*

*D. bipectinata* observed in a natural population. Structural changes in chromosome, like deletion, duplication, inversions, and translocation, are known to occur in humans as well as plant and animal species. Inversions are the most common structural changes in chromosome. As a result of inversion, the order of the segment gene is inverted. Chromosomal inversions were the first type of genetic variations to be studied in *Drosophila* due to the involvement of an inversion. The occurrence of inversions in the polytene chromosome of *Drosophila* can be clearly observed and has been extensively studied from time to time in its different species of this group.

Generally, inversions are generated by the non-allelic homologous between inverted repeats, but in some other species like human, DNA repair mechanisms also involve originated inversions i.e., double-strand repair mechanisms like non-homologous end joining and replication-based repair mechanism. However, in most of the cases, there is no effect on gain and loss of DNA (Puig et al. 2015).

Chromosomal inversions aberration can be observed as inversion heterozygotes (ST/In) always manifested in the form of a loop in the polytene chromosome, and inversion homozygote (In/In) observed as the polytene chromosome is in a permanently paired state.

There can be two types on inversions based on the presence of centromere, the inverted segment includes the centromere, then such inversion is referred to as pericentric inversion, and

paracentric inversions are those which do not include centromere. Pericentric inversions were observed in plant, grasshopper, and crickets and have been extensively studied in grasshopper from Australia and have been discussed from an evolutionary point of view. Paracentric inversions are very common and occur at a high frequency in a number of species due to their adaptive significance for them and have been widely studied in genus *Drosophila* (Singh and Singh 2018; Singh 2019). However, translocation and pericentric inversions are very rarely reported in *Drosophila* (Singh and Singh 2015).

Inversions which occur frequently in a species are described as cosmopolitan, and their frequency always remains higher than other inversions in every population. The inversions remaining at very low frequency, i.e., less than 5% but present in most of the populations, are called rare cosmopolitan. Some inversions are occurring in some individuals of a population, described as rarely occurring inversions.

A number of species of the genus *Drosophila* have been investigated for their chromosomal polymorphism like *D. melanogaster*, *D. ananassae*, *D. bipectinata* species complex, *D. pseudoobscura*, *D. willistoni*, *D. subobscura*, *D. nasuta*, etc.

Fixation or elimination, distribution, and frequency of an inversion in a population depend on their phenotype consequences and mostly on the evolutionary forces such as natural selection and genetic drift.

## Role of Inversion

On the basis of recent theory and data that are observed by some population, geneticists addressed the potential role of inversion in speciation and evolution. Basic population genetics marker to check the genetic variations between different species of a group or genus is chromosome inversion, and it has significantly affected the rate of adaptation, survival, mating success, rate of development, competitive ability, fecundity, longevity, fertility, etc. (Sperlich and Pfriem 1986). Inversions have been involved affecting the phenotype in multiple species: in *Drosophila* inversions can affect the size

and development time: flowering in plants or adaptation to freshwater in stickleback.

Based on the inversion polymorphism, recently some studies have been conducted to understand the impact of inversions on evolution because an inversion present in a natural population, after several generations in laboratory, may be lost or present in a polymorphic state.

In many nondrosophilids species like black flies and seaweed flies, inversion polymorphisms may influence development time, size, and viability; however, effects on these traits also vary with environmental conditions (Butlin and Day 1989). Blyth and Gilburn (2005) also observed the role of chromosome inversion on sperm displacement in seaweed flies and concluded that when female mates rapidly, sperm carrying opposite karyotypes are favored and increase the higher number of heterokaryotypic offspring. Colombo (2002) and Pensel and Remis (2007) studied the role of pericentric inversions at body size and lifespan of the male of New World grasshopper. The body size is similar in higher latitude and altitude individuals, but the frequencies of inversion polymorphism changed between beginning and end of the adult lifespan, and the survival is more in the highly polymorphic males.

*Anopheles gambiae* complex have some insecticide resistance influencing genes that present on the two paracentric inversions, i.e., 2La and 2Rb, associated with dieldrin and DDT resistance, respectively (White et al. 2007a, b). Hardikar and Nath (2001) suggested that inverted heterozygotes tropical midge, *Chironomus ramosus*, have lower chances of infection with nematodes than homozygotes, and heterozygosity is also associated with the larval size in midge.

## Inversions and *Drosophila*

Genetic marker and inversion both were used as marker in cytological studies. Inversion polymorphism has been used in many species of *Drosophila* to test suppressive effect on recombination, heterosis, size, and time of development (Yadav and Singh 2006). The suppressive effects of inversion on recombination have been first time

observed in *D. melanogaster*. The effect of heterozygous superiority of inversion in different species of *Drosophila* was observed. For example, in *D. pseudoobscura* heterozygosity of inversion prevents the recombination in the chromosome (Dobzhansky and Epling 1948), in *D. melanogaster* heterozygous inversion of X chromosome shows same situation, and Grell (1962) also observed heterozygous inversion in *D. melanogaster* that increases the frequency of crossing over in X chromosome. Some other observations in different species of *Drosophila* show that X-chromosome heterozygous inversions enhance the effect of recombination in the autosome. Inversion polymorphism is a most important traditional marker in population genetics to discuss the phylogenetic relationship between the different members of a species complex (Tomimura et al. 2005; Banerjee and Singh 2016). Singh and Singh (1987) suggested that recombination is also influenced by the heterozygosity of inversion in *D. ananassae*. It has also been observed that the larger size of heterozygous inversion increases the frequency of crossing over in chromosome. Inversion polymorphism plays a crucial role in some adaptive traits. Mating propensity is one of them that is associated with inversions, and it has been demonstrated in many species of *Drosophila*. Singh and Chatterjee (1986) observed mating ability of different inversion karyotypes in *D. ananassae*, and they concluded that heterosis was associated with male mating ability, and inversion occurring in high frequency in a population was associated with higher mating ability.

## Inversions and Human

The existence of inversions in humans has been long known during the time of primate evolution and speciation. After a long time, still we have not much information about the presence of polymorphic inversions in the human chromosome and the significant association of inversions with gene expression, adaption, disease, or recombination (Feuk et al. 2005).

It's very difficult to detect and identify inversions in the human genome; some cytogenetic techniques and molecular tools like G-banded karyotypes, fluorescence in situ hybridization,

Southern blot hybridization, or pulsed-field gel electrophoresis help us to observed human inversion. In the human genome, many identified inversions do not have association with any phenotypic effect, but some of them significantly have been related to several diseases.

Some paracentric inversions in human directly affect the frequencies in different human populations. For example, pericentric inversion in chromosome 9 (mainly heterochromatic sequences inverted) shows the variation in frequencies in different populations from 0.26% to 3.57% in Asian and African origin, respectively (Thomas et al. 2008). Besides this, some other few inversions have been responsible for some diseases, such as hemophilia A and Hunter syndrome. Two types of inversions presented on the X chromosome have been involved in familial hemophilia A in which mutation is inherited in offspring by a male patient from an unaffected mother (Antonarakis et al. 1995). The common cause of Hunter syndrome in human is the alteration in the X-chromosome-linked IDS-related sequences by an inversion of the IDS gene, which encodes the iduronate-2-sulfatase enzyme (Bondeson et al. 1995).

Based on the cytogenetic and traditional molecular approaches and evidence in multiple species including human indicated that inversion can directly influence, alter, and affect the gene and their expression by regulating different levels. However, most of the inversions have not been observed for their effect on the human genome. Based on the mating propensity, it is concluded that the inversions may assist the evolution of sex chromosome by influencing recombination between sex chromosome and alleles which have sex-specific effects.

## Invisible Displacement

Rebecca Singer

Georgetown College, Georgetown, KY, USA

### Synonyms

[Object permanence](#)

### Definition

Invisible displacement is the ability to track the movement of a hidden object after seeing that object placed in, under, or behind an occluder and moved into or behind a second occluder.

### Introduction

Invisible displacement is the sixth, and final, stage of object permanence ability. Object permanence is the understanding that objects exist even when they cannot be directly perceived. Piaget (1954) proposed that human children develop object permanence during the sensorimotor period of development and that this skill developed slowly over six stages. In the first stage, human infants show no response to the disappearance of an object. Infants in stage 2 will track an object of interest that is visible, but will not follow the object once it is out of sight. Further, they show no anticipation of where the object would logically be once it moves out of sight. By stage 3, children can locate partially hidden objects such as a toy that is sticking out from under a blanket. Children will successfully retrieve fully hidden objects in stage 4. This is visible displacement. By the fifth stage, children are capable of finding an object where it was the most recently hidden without making a typical error called the A-not-B error. This is when children will look at in a familiar hiding location even when they witness an object hidden in a new container. The sixth stage of object permanence development involves seeing an object hidden under a displacement device and

then moved to a new hiding location. The object is surreptitiously placed in the new location and the empty displacement device is shown to the child. This is invisible displacement. Children who have mastered stage 6 object permanence are able to track the movement of the hidden object and correctly locate it in the new location.

### Testing Methodology

Invisible displacement ability is tested through one of three basic tasks. These include a containment task, a rotation task, and a transposition task.

#### Standard Piagetian Task

The standard test for invisible displacement involves hiding an object inside a displacement device. This can be any opaque container. Next, the displacement device is placed inside one of several opaque containers. The object is surreptitiously removed from the displacement device and the device is removed. Subjects see the empty displacement device. Successful completion of this task involves indicating which opaque container contains the hidden object. An example of this would be to show a child a piece of candy and then wrap it inside a fist. The hand is then placed into a pocket and the candy is released. Upon seeing an empty hand, a child would indicate that the candy was in the pocket.

#### Rotation

Rotation tasks can also be used to assess whether an individual can track the movement of a hidden object. In this type of task, an object is hidden inside one of two opaque containers. The two containers are then moved with a rotating mechanism such that containers 1 and 2 switch places (a 180° switch). Other rotations tasks involve only a 90° rotation of the containers (e.g., Miller et al. 2009). The goal is to identify where the hidden object is after the containers stop moving.

#### Transposition

Transposition involves hiding an object inside one of several opaque containers. Then the container itself is moved to a new location. Subjects

must indicate where the hidden object is in the new location.

## Invisible Displacement in Animals

The literature is mixed on the question of whether animals other than nonhuman primates are capable of solving invisible displacement tasks. Several species of birds, dogs, cats, dolphins, prosimians, lesser apes, and great apes have all been tested using one or more of the methodologies described above (see Jaakkola 2014 for a thorough review). The evidence suggests that many primate species demonstrate invisible displacement capacity (e.g., Call 2003). Some studies suggest that adult dogs are capable of invisible displacement (e.g., Zentall and Pattison 2016). However, there are also numerous studies that suggest the dogs' success was merely the result of simpler, associative rules (e.g., Collier-Baker et al. 2004). For example, animals may be able to use a rule such as "*Pick the last container touched,*" "*Pick the container the experimenter is near,*" or "*Go to the container closest to the displacement device.*" Further, animals that attend to social cues may solve invisible displacement tasks by using eye gaze or body orientation of the experimenter. One solution to this problem would be to "blind" the experimenter by having them look away from the apparatus, shield their eyes, or hide completely out of sight of the research subject. A final concern is that the tasks designed to test invisible displacement to date have not been ecologically relevant. It has been suggested that if animals were given a task that was more natural, they may be more likely to pass the invisible displacement task. For example, Jaakkola et al. (2010) reported failure of their dolphins to pass invisible displacement using a traditional containment procedure. However, Johnson et al. (2015) used an occlusion task rather than a containment procedure and their results indicate that indeed, dolphins were capable of solving invisible displacement. The occlusion task was more natural for a dolphin than a containment task.

## Conclusion

Invisible displacement is the most complex stage of object permanence. While many animals are capable of the earlier stages of object permanence such as visible displacement, very few are able to solve invisible displacement tasks when appropriate controls are used to prevent the use of social or sensory cues and associative rule learning. Thus far, the great apes, and perhaps dolphins, appear to be the only species, other than humans, that consistently pass.

## **IQ**

Louis D. Matzel and Bruno Sauce

Piscataway, NJ, USA

### **Introduction**

Intelligence is the ability to think rationally, learn effectively, understand complex ideas, and adapt to the environment. Accordingly, intelligence is best seen as a general ability that can influence performance on a wide range of cognitive tasks. IQ (the intelligence quotient) is the quantification of an individual's intelligence relative to peers of a similar age. IQ is one of the most heritable psychological traits, and an individual's score on a modern IQ test is a good predictor of many life outcomes, including educational and career success, health, longevity, and even happiness (Gottfredson 1998). Like humans, several species of animals express a "general cognitive ability" that influences performance on broad and diverse cognitive tasks, and moreover, animals exhibit a wide range of individual variations in this ability.

### **Intelligence and Intelligence Testing (IQ) in Humans**

It has long been recognized that intelligence varies across individuals. Colloquially, we refer to someone as "brilliant" or comment that our dog is a "little dull." While it is easy (and common) to make these kind of characterizations, it has historically been difficult to formulate a definition of this trait. In 1995, a committee of the American Psychological Association stated that "Individuals differ from one another in their ability to understand complex ideas, to adapt effectively to the environment, to learn from experience, to engage in various forms of reasoning, to overcome obstacles by taking thought. Concepts of 'intelligence' are attempts to clarify and organize this complex set of phenomena" (Neisser et al. 1996). In an article in the Wall Street Journal

(December 13, 1994) signed by 52 intelligence researchers, it was asserted that intelligence was "a very general mental capability that, among other things, involves the ability to reason, plan, solve problems, think abstractly, comprehend complex ideas, learn quickly and learn from experience. It reflects a broader and deeper capability for comprehending our surroundings."

The above definitions are simultaneously vague and broad. Although provided by experts on intelligence, they differ little (if only in form) from colloquial descriptions of the trait that one might hear from a random sample of college undergraduates. While it has been more than 100 years since Spearman (1904) formally described the concept of "general intelligence" (also called "g"), we still struggle with its definition, but nevertheless, we recognize it and we make inferences about its consequences. In this regard, the *quantification* of intelligence is best relegated to performance on psychometric tests. The rationale for most psychometric tests is roughly based on Spearman's early observation that performance on a wide range of cognitive tasks is positively correlated (i.e., if you perform well on one, you tend to perform well on others) and, as such, can be reduced to a single index of aggregate performance across a battery of diverse tests. In fact, psychometric tests (e.g., the Stanford-Binet, the Wechsler or WAIS, and the Raven's Progressive Matrixes or RPM) do differ in their content and structure. For instance, the Stanford-Binet includes questions that are culturally relevant and thus is best suited to predict performance in a particular culture's school system. The WAIS is less culturally biased but, like the Stanford-Binet, includes categories of questions that are presumed to reflect domains of abilities (verbal comprehension, working memory, perceptual reasoning, processing speed). An individual's performance on tests within a particular domain (e.g., reasoning) tends to be highly correlated, while performance on tests across domains (e.g., a reasoning task and a spatial task) is usually less correlated. Nevertheless, positive correlations are observed between performance on *all* tests in

the battery. This is in line with the conclusion that *all* cognitive abilities are regulated (to varying degrees) by one general factor, or Spearman’s “g,” while other specific abilities might influence performance within a particular domain. These kinds of observations have led to the development of hierarchical models regarding the structure of intelligence, where *g* influences domains of specific abilities, which influence tasks within those domains. An illustration of a hierarchical model is provided in Fig. 1.

Since many studies on intelligence use factors analyses, a brief explanation of this technique is warranted. Briefly, a factor analysis is a statistical method which reduces a large number of correlations into as few explanatory factors as possible. If, for example, all of the correlations across several tests of cognitive ability are strongly positive, the factor analysis recognizes that a common source of variance contributed to performance on all tasks, and this would be described as a general factor. In reality, the outcome of such an analysis can be much more complicated, and of course we might be interested in large numbers of cognitive tasks, some of which represent clusters of what are

presumed to be specialized abilities. In these cases, the factor analysis might extract a general factor, as well as secondary factors, which explain relationships between only subsets of the tasks being considered. Of course, if no single source of variance was common to all tasks, a factor analysis might reveal no common factor at all. When factor analyses are performed on human intelligence test data (such as from the WAIS), it is typical to find a general factor (i.e., general intelligence) as well as secondary factors that describe specific cognitive domains (e.g., spatial abilities; see Fig. 1).

Remember that the Stanford-Binet and the WAIS include tests of many different abilities, and an individual’s aggregate performance across all of these tests is used to estimate that individual’s intelligence. In contrast, the RPM is an intelligence test that is based exclusively on only *one* ability and, accordingly, includes only progressively difficult tests of perceptual (analogical) reasoning. This test structure is based on an assumption that reasoning is representative of *the* core ability that regulates all intelligence (Raven et al. 1998). Because of its

**IQ, Fig. 1 The hierarchical model of intelligence.** *Level 1* represents specific tests that are emblematic of various domains of cognitive ability. Some potential domains are illustrated in *Level 2*. The number and content of these domains is a matter of some debate, although there is wide agreement on the existence of the four domains that are illustrated. The fifth domain (?) acknowledges that other domains may exist. People who perform well on tasks from

one domain tend to perform well on tasks from other domains. This suggests the existence of a general influence on cognitive abilities, represented in *Level 3*. This general influence is commonly referred to as general intelligence or simply “intelligence.” This model does not require only *one* type of intelligence. Rather, it assumes that a general ability influence other more domain-specific abilities.

format, the RPM requires no knowledge of culture or language.

Unlike a qualitative description of intelligence, the IQ *score* is a *quotient*, that is, it is an individual's score on a standardized test *relative* to that individual's age-matched peers. It is true that an individual's IQ score will tend to remain stable across the lifespan, i.e., the IQ scores of a group of 8-year-olds will be highly correlated with their scores at 90 years of age ( $r = \sim .80$ ). This does *not* mean that individual's raw cognitive ability is the same across the lifespan. For example, were we to administer an RPM to one individual at 8, 25, 50, and 90 years of age, the number of correct answers would be about the same at 8 and 90 years of age, while at 25, the individual would answer at least twice as many questions correctly (with the 50-year-old somewhere in between). So why do we say that an individual's IQ remains constant across the lifespan? Because IQ is approximately unchanging *relative* to persons of a similar age, i.e., a person who is smarter than most of his/her peers at 8 years of age will be smarter than his/her peers at 50 and 90 years of age (Deary 2014), despite the inevitable truth that our cognitive abilities decline with age.

Regarding the nature of intelligence or IQ, many persons will incorrectly assume that high intelligence is necessarily reflected in a high level of *knowledge*. In fact, high intelligence promotes the ease with which we acquire knowledge, but intelligence itself is independent of knowledge. Why then do some IQ tests (such as the Stanford-Binet) have components that test knowledge? Simply because all other things being equal, a smarter individual is likely to acquire more knowledge. Learning is *easier* for that individual than it might be to someone of lesser intelligence. In this regard, scholastic aptitude tests such as the SAT are often a good approximation of intelligence as measured on a knowledge-free test such as the RPM ( $r = .5-.6$ ). However, knowledge and intelligence need not always be related. For instance, an individual with innately high intelligence might (through some act of fate) live in an impoverished environment where the opportunities to acquire knowledge are severely limited. This is exactly why an IQ test such as the

RPM has no measures of knowledge (only perceptual reasoning) and is considered by many to be a more pure measure of innate ability.

Given the different content and structure of psychometric intelligence tests, it might be surprising to find that individuals' scores on these tests are strongly correlated ( $r$ s will typically range from 0.8 to 0.9). Even more surprising is the popular assertion (sometimes even by some with advanced degrees in psychology) that "IQ tests measure nothing of functional significance." Standardized intelligence tests first received widespread recognition owing to the US government's use of a modified version of the early Stanford-Binet to determine assignments of new recruits in World War I. These assignments were highly effective (relative to the previous practice of assignments based on patronage or chance) and are widely regarded as having contributed to the USA's success in WWI. Since that time, we have collected a wide array of data regarding the predictive capacity of IQ tests. For instance, a child's IQ score is highly predictive of obvious outcomes such as educational and career success, as well as lifetime income. But IQ test performance predicts many less obvious outcomes such as the distance one will travel from his/her place of birth, the likelihood of incarceration, the likelihood of drug addiction, the age of death, incidence of type II diabetes, ratings of happiness, and even your *spouse's* income and IQ (for a comprehensive review of the predictive capacity of the IQ test, see Gottfredson 1998). IQ scores are even inversely related to the likelihood that an individual will murder their spouse! To quote Gottfredson (1998, page 24), "No matter their form or content, tests of mental skills invariably point to the existence of a global factor that permeates all aspects of cognition. This factor seems to have considerable influence on a person's practical quality of life. Intelligence as measured by IQ tests is the single most effective predictor known of individual performance at school and on the job" as well as many other aspects of well-being. Thus, far from being a "social construct" with no functional significance, the modern IQ test is a highly effective (and widely used) diagnostic and predictive tool.

### Intelligence in Nonhuman Animals

Although studies of individual differences in animal intelligence had been frequent early in the twentieth century (Thorndike 1911, 1935; Tolman 1924; Tryon 1940), the emergent focus on experimental (rather than correlational) studies tended to limit the interest in this topic in the later part of that century. However, during the past two decades, interest in individual differences in animal intelligence has seen a dramatic reemergence. As discussed above, contemporary definitions of intelligence tend to be vague, broad, and, to some degree, a matter of debate (Sternberg 1985). Nevertheless, psychometric tests of intelligence do appear to characterize a trait captured in both colloquial and empirical definitions of intelligence, i.e., the ability to understand, learn, and reason. To explore a trait analogous to intelligence in nonhuman animals, researchers have developed tests to characterize a similar set of skills, most notably in mice and monkeys.

Genetically heterogeneous mice (i.e., mice with genetic variability that translates into measurable individual differences) have been tested on large batteries of cognitive tasks to determine the existence of a general cognitive ability in mice analogous to IQ. In one such study (Kolata et al. 2008), 241 mice were tested on seven cognitive tasks, which included tests of working memory capacity, associative learning, operant learning, and spatial learning abilities. Using factor analysis, it was observed that a general factor influenced performance in these mice and this factor accounted for 38% of the variance across tasks. This is comparable to what is known from tests of humans' abilities, where it is believed that general intelligence accounts for 40–50% of the variance in performance across a broad array of cognitive tests. In addition, a domain-specific factor was found to account for the performance of mice on a subset of tasks that shared a dependence on spatial processing. These results provide evidence for a general learning/cognitive factor in genetically heterogeneous mice. Furthermore (and similar to human cognitive performance), these results suggest a hierarchical structure (see Fig. 1) of cognitive abilities in mice, where a general factor influences performance on sub-

domains of abilities. Importantly, mice also exhibited considerable variability in their general cognitive performance. In fact, the general abilities of mice were normally distributed, such that most mice expressed average abilities, while some were “bright” (performing well on all tasks), while some were “dull” (performing poorly on all tasks).

As described above, reasoning is considered to be a hallmark of intelligence and is considered by some to be *the* general factor that underlies variations in intelligence. It has previously been established that humans are capable of “fast mapping” (Carey and Bartlett 1978), a process whereby a new concept can be acquired based on a logical inference, corresponding with Aristotle's description of deductive reasoning. Fast mapping is believed to play a critical role in the extraordinarily rapid acquisition of information during early human development and explains (in part) the prodigious rate at which children gain vocabulary. For example, when faced with a group of familiar items described by familiar words, an infant will quickly associate an unfamiliar word with a novel item added to the set of familiar items, and this association requires no overt “pairing” of the novel word and its corresponding novel item.

Fast mapping based on responses to human language has also been demonstrated in dogs (Tomasello and Kaminski 2004; Pilley and Reid 2011), where border collies can successfully find a novel object when commanded (with a novel word) to retrieve that novel object from within a large set of familiar objects. Using a similar strategy, fast mapping has been assessed in mice, although the task was not based on responses to language. Mice were first trained to associate pairs of objects, where, upon exposure to a sample object, the correct choice of a target object earned the mouse a food reward. Following training, the mice could successfully use the sample object to guide its choice of a target object out of a set of familiar objects. (This type of performance is emblematic of “paired associate learning.”) To test “fast mapping,” the animal was then presented with a novel sample object and allowed to choose a target object from a set containing several familiar objects and one novel object. If the mice were

capable of fast mapping (inference by exclusion), they should choose the novel target object (in response to the novel sample) since all other objects in the set had a previously established meaning. Mice perform quite well in this task, choosing the novel object at an average rate far better than chance. However, not all mice perform similarly, and while some exhibit perfect performance, some consistently make incorrect choices. The likelihood of a mouse's success in this fast mapping task is correlated with their performance on other more elemental cognitive tasks (e.g., associative learning, spatial learning, operant learning), suggesting that as in humans, this form of reasoning ability is related to more general cognitive abilities (Wass et al. 2012).

General cognitive abilities of mice have also been described by Galsworthy et al. (2002), who compared the performance of 40 genetically heterogeneous mice across a battery of cognitive tests distinct from those reported in the studies described above. All measures of cognitive performance loaded positively on a principal component that accounted for 31% of the variance across mice, again suggesting the presence of a common influence on performance on all tasks. In addition, Galsworthy et al. calculated the heritability of this general cognitive ability in mice. (This was accomplished through a classic sibling analysis, which assesses the degree of relatedness between siblings on some variable of interest, in this case general cognitive ability.) The heritability of the general cognitive ability of mice was estimated at approximately 0.4 (on a scale of 0–1), suggesting a moderate genetic contribution to the expression of this trait. These results of Galsworthy et al. are quite informative. They indicate that the “intelligence” of mice is moderately heritable, at a level that is comparable to what is observed among teenage humans. Note that the heritability of human intelligence actually *increases* across the lifespan, reaching a plateau of approximately .80 at 50 years of age. This increase in heritability is presumed to reflect the interactions of genes with the environment, where persons of similar IQ become even *more* similar as they gravitate to similar cognitive challenges. Unlike typical humans, laboratory mice are maintained in a

behaviorally sterile and homogeneous environment. Consequently, these mice cannot select the environments or challenges that might maximize cognitive differences, thus constraining the gene-environment interaction.

In addition to rodents, individual differences in a general cognitive ability have been observed in several species of nonhuman primates. While most studies of nonhuman primates have been designed to compare differences in intelligence between species (leading to a popular hypothesis that brain size is related to intelligence; Burkart et al. 2016), at least one study was designed explicitly to assess individual differences in the expression of a general cognitive influence within a single species. Banerjee et al. (2009) administered a large and diverse battery of cognitive tests to 22 tamarin monkeys (*Saguinus oedipus*). The cognitive tasks covered a wide range of cognitive skills and domains, including occluded reach, targeted reach (reward retrieval from a moving pendulum), adaptation to an observed change in reward location (a measure of executive control), reversal learning, novel object recognition, numerical discrimination, acoustic habituation, object tracking (an index of attention), social tracking (gaze at a conspecific), hidden reward retrieval after various delays, and a food retrieval puzzle (which was asserted to tax reasoning). Banerjee et al. observed positive correlations in the monkeys' performance across all tasks. Using a type of factor analysis, all tasks loaded positively on a common factor. The weight of these loadings (an index of the degree to which a variable is impacted by that factor) could be described as “weak” to “moderate.” Expectedly, the tasks with the least obvious cognitive demands (targeted reach and social tracking) loaded most weakly. In total, these results provide evidence for individual differences in the expression of a general cognitive ability among tamarins, and moreover, that the general factor's influence is directly related to the level of the cognitive demand.

### What is the Latent Factor that Regulates Intelligence?

Many factors, such as speed of processing or brain size, have been suggested to underlie variations in

intelligence. However, correlational analyses have typically found only weak relationships between these factors and intelligence. Two clear exceptions should be noted. Both reasoning ability and working memory capacity are strongly predictive of IQ (and as noted previously, the RPM intelligence test is based solely on performance on analogical reasoning tasks). Although it was once commonly asserted that reasoning ability was *the* latent factor which regulated individual differences in intelligence, it has been more recently hypothesized that working memory may serve such a function. In his classic textbook on intelligence, Mackintosh describes the full rationale for this hypothesis and points out that it is easy to surmise the way that working memory could influence reasoning, as will be seen below, while it is more difficult to imagine the opposite being true (Mackintosh 1998).

Since their inception, intelligence test batteries commonly included tests of simple memory span (e.g., the number of items from a briefly studied list that an individual can correctly recall). Somewhat surprisingly though, this seemingly elemental ability has only a weak relationship to general intelligence. In 1980, an important observation by Daneman and Carpenter (1980) shed light on the relationship between memory and intelligence. Daneman and Carpenter found that simply remembering a list of words was only weakly related to general intelligence (in this case, estimated through reading comprehension). In contrast, if the same words appeared at the end of sentences, the ability to remember those words was strongly correlated with general intelligence. This led to the hypothesis that simple retention had only a small (if any) role in the regulation of intelligence, while “working memory capacity” had a more central role.

While short-term memory simply holds information, the working memory system is one which stores information while manipulating and utilizing that information (often during conditions of high interference) for a particular goal. Working memory is employed for most cognitive tasks. For instance, your ability to read and comprehend this paragraph requires that you remember words, synthesize the meaning of strings of words, and

try to extract the overall message embedded in those strings of words. Obviously, your memory and manipulation of words and thoughts can become confused depending on the content of the paragraph. A similar rationale for the implementation of working memory can be applied to virtually any task; imagine doing a mental math problem or solving a spatial puzzle. In this regard, an analogical reasoning problem (such as might appear on the RPM test of intelligence) requires the individual to hold potential solutions in memory, compare the utility of those solutions, revise the solutions, and store the revised solutions in temporary memory. But while analogical reasoning depends on the efficient application of working memory, it is not clear that the application of working memory has any dependence on reasoning abilities. It is this ubiquitous demand for working memory that has led to the assertion that working memory may be the basis for the overall performance on an intelligence test. Since the original report of Daneman and Carpenter, many studies have found evidence for the relationship of working memory capacity to general intelligence (for a brief review, see Engle 2002).

Unlike human research, only limited work has been done to assess the relationship between working memory and intelligence in nonhuman animals. Some studies have found a relationship between working memory and intelligence in mice, but such correlations cannot be assumed to reflect a cause-and-effect relationship. The direction of cause between working memory and intelligence cannot be determined, and moreover, both traits might be influenced by a third, hidden variable. It should be noted that the same difficulties exist when interpreting this relationship in humans. However, in both humans and mice, a causal relationship between working memory and intelligence has been explored. For instance, Jaeggi et al. (2008) exposed humans to intensive working memory training by having them perform a “dual n-back” task for several weeks. The dual n-back task requires the subject to simultaneously monitor a stream of visual and auditory cues (a sequence of visual locations and a sequence of auditory letters). The subject’s task

is to identify matches that occur in each stream of information (e.g., auditory “B” matches auditory “B,” or upper right grid location matches upper right grid location) that occur a specific number of places back in the stream of information, e.g., 2-back, 3-back, and 4-back. Humans typically find this task to be extremely difficult (and even stressful), and the larger the n-back requirement (e.g., 4-back rather than 2-back), the more difficult the task becomes. This task is considered to tax working memory capacity, and humans will typically improve across days of training; they may initially find 2-back to be *very* difficult but might eventually master 6-back. Jaeggi et al. observed that several weeks of such training improved working memory and had positive (although small) effects on intelligence test performance. This suggests that working memory has a direct *causal* influence on an individual’s intelligence.

The work by Jaeggi et al. (2008) is by no means conclusive. While it has been replicated several times, others have failed to replicate these results, often after extensive attempts to do so (Redick et al. 2012; Shipstead et al. 2012). Relatedly, commercial “brain training” devices based on working memory training have been widely criticized as ineffective (Simons et al. 2016). Although this controversy has not been resolved, it is clear that training working memory in humans is complicated by the fact that humans *regularly* engage in the use of working memory outside of the laboratory (e.g., your comprehension of this paragraph), and so any working memory training that occurs in the laboratory is small in comparison. To this end, it might be useful to consider the effects of working memory training on laboratory animals that live in sterile cognitive environments. Light et al. (2010) developed a task to train working memory in mice. In this task, the mice were required to perform simultaneously in two mazes, and each maze required the animals to keep track of eight locations. Since the locations were marked by a common set of visual cues, the mice become very confused (presumably owing to an overload of working memory). Like n-back training, mice get better at these mazes over a period of weeks and, when later tested, exhibit

improvements in working memory. Likewise, they exhibit improvements in general cognitive performance, suggesting that the efficacy of working memory can under certain circumstances have a direct causal impact on a mouse’s intelligence. In the case of both humans and mice, these studies of the impact of working memory training on intelligence provide further evidence that intelligence is *malleable*. That is, although intelligence is heritable, genes interact with environmental experience to regulate an individual’s IQ.

Space does not permit a detailed explanation of the neuroanatomical systems that contribute to the expression of intelligence or working memory. However, these kinds of analyses also suggest that these abilities are strongly related. Brain areas that are active during tests of general intelligence overlap considerably with brain areas active during performance of a working memory task (Jung and Haier 2007), and the same brain areas have been implicated in the processing of working memory in both monkeys (Konecky et al. 2017; Riley and Constantinidis 2015) and rodents (Wass et al. 2013). In total, and although this issue is far from resolved, our current state of understanding suggests that variations in working memory capacity contribute directly (at least in part) to variations in intelligence.

## Conclusion

Humans and nonhuman animals exhibit individual differences in their ability to “reason, plan, solve problems, think abstractly, comprehend complex ideas, learn quickly and learn from experience” (Neisser et al. 1996). This complex of abilities is referred to as intelligence. In both humans and animals, this trait can be assessed through batteries of cognitive tests, and in humans, these tests give rise to an intelligence quotient (an “IQ score”) which quantifies an individual’s performance *relative* to those of a similar age. Studies in nonhuman animals, most remarkably in primates and mice, have utilized diverse batteries of cognitive tests to measure something analogous to IQ. The intelligence in these animals varies among individuals and seems to be

correlated with processes such as reasoning and working memory. Recent research in both humans and mice suggest that working memory training might make causal contributions to the improvement of IQ. Those findings have not only theoretical implications concerning the structure and neurobiological insatiation of intelligence, but it also opens up opportunities for future practical applications.

## Irene M. Pepperberg, PhD

Irene M. Pepperberg  
Department of Psychology, Harvard University,  
Cambridge, MA, USA

### Research Interests

Pepperberg was the first to demonstrate that Grey parrots learn best through social interaction and that their abilities with respect to various concepts (e.g., number, relative size, same/different, inferential reasoning by exclusion) are equivalent to those of nonhuman primates, cetaceans, and ~5–6-year-old children. To teach her parrots referential use of English speech, she departed from the standard operant methods in use at the time and adapted Todt's (1975) two-person “model/rival” training technique, by alternating the roles of the person who modeled what the parrot was to learn with that of the person acting as respondent and using referential rewards – a 1:1 correspondence between the label to be trained and the object presented to the parrot for its use of that label. Via this technique, a Grey parrot, Alex,

learned to label more than 50 different objects, seven colors, and seven different shapes (“one-”, “two-”, “three-”, “four-”, “five-”, “six-”, or “eight-corner”). He learned to use English number labels (“one” through “eight”) to distinguish quantities of objects, including collections made up of novel objects, heterogeneous sets of objects, and sets in which objects were placed in random arrays. He could perform addition on small sets and with Arabic numerals. He induced the ordinality of his known numbers from their value and the cardinality of new number labels from their position on the number line. He combined his vocal labels to identify proficiently, request, refuse, categorize, and quantify over 100 different objects, including those that varied somewhat from his training exemplars. He had functional use of “no” and of phrases such as “come here,” “want X,” and “wanna go Y” (X, Y being appropriate object or location labels). He fully understood the concept of same/different: not merely identity versus nonidentity but that two objects could simultaneously be the same with respect to some attributes and different with respect to others. He and another Grey, Griffin, demonstrated, by vocally stating what they saw, the ability to interpret optical illusions (Müller-Lyer, Kanizsa figures, occluded figures) as do humans. Grey parrots have also used English speech in ways that allowed an examination of other advanced cognitive abilities, such as probabilistic inference. Pepperberg has shown that Grey parrots have executive functioning equivalent to that of young children (e.g., by passing the “marshmallow test”).

### Early Life, Educational Background

Dr. Pepperberg was born on April 1, 1949, in Brooklyn, NY, and raised in Laurelton (Queens), NY. An early interest in science was fostered by teachers at Andrew Jackson High School. She received a Bachelor of Science in Chemistry from MIT (1969) and a PhD in Chemical Physics at Harvard from the soon-to-be Nobel Laureate, William N. Lipscomb (1976). During her graduate career, she published several papers on molecular

orbital theory and boron hydrides. While at Harvard, she realized that her long-standing interest in animal behavior was stronger than her interest in theoretical chemistry. She began attending seminars and auditing courses on the communicative behavior of animals in nature, avian biology, interspecies communication, and on language acquisition in humans, working up to 80 h per week so as not to neglect her doctoral studies. After completing her doctorate, she switched fields completely.

## Professional Career

Moving with her then-husband, Dr. Pepperberg began her career in 1977 at Purdue University, as a research associate in biology and part-time instructor in psychology. With space borrowed from members of the biology department and the purchase of a Grey parrot, she began conducting experiments on interspecies communication and conceptual behavior in an avian subject. Despite the absence of a faculty appointment, she received the first of many NSF grants in 1979 and later a Harry Frank Guggenheim Foundation Fellowship. In 1984, she became a visiting assistant professor in the Anthropology Department at Northwestern University and a member of their Program on Language and Cognition. She remained at Northwestern until January 1991. At that time, she assumed an associate professorship in the Department of Ecology and Evolutionary Biology at the University of Arizona, receiving tenure in May 1994. She concurrently had a faculty appointment in the Department of Psychology and was an affiliate in the Program in Neuroscience. While at Arizona, she took a leave of absence (1999–2001) to work at the MIT Media Lab to design human-animal-computer and animal-computer interfaces and to explore the use of her research in building intelligent learning systems. Her visit developed into a research position that ended because of budgetary cutbacks at the Lab. To compensate for breaking her contract, MIT created a short-term research situation to enable her to continue her work; the parrot lab moved to Brandeis University,

where she was a research associate professor and later an adjunct associate professor until 2013. After a Radcliffe Fellowship (2004–2005), she was invited to join the Vision Lab at Harvard as an unpaid research associate. She began teaching at Harvard in various capacities soon thereafter. Her research since MIT has been supported by two NSF grants and *The Alex Foundation*, a 501(c)(3) nonprofit of which she is the president. In 2013, she moved the parrot laboratory to Harvard's Department of Psychology.

While at the University of Arizona, Dr. Pepperberg was the recipient of numerous awards for teaching and student mentoring and received a John Simon Guggenheim Fellowship. She was made a fellow of the American Psychological Association, the American Psychological Society (now the Association for Psychological Science), the Animal Behavior Society, and the American Ornithologists' Union, was an alternate for the Cattell Award for Psychology, and was nominated for the Weizmann Woman and Science Award.

While at MIT, Dr. Pepperberg received the 2000 Selby Fellowship from the Australian Academy of Sciences, was made a fellow of the American Association for the Advancement of Science (AAAS), and was nominated for the Grawemeyer Award in Psychology, the L'Oreal Women in Science Award, and the Quest Award from the Animal Behavior Society.

Since arriving at Harvard, she has won the 2005 Frank A. Beach Award, given by Division 6 of the American Psychological Association for best paper in the *Journal of Comparative Psychology*; the Christopher Award for her *New York Times* best-selling book, *Alex & Me*; and the Christopher Clavius S.J. (Sigma Xi) Award from St. Joseph's University. She was a consultant for ITALK (2007–2012), a program for robotics research. She became a fellow of the Eastern and Midwestern Psychological Associations, was renominated for the L'Oreal and Grawemeyer Awards, and was nominated for the Hebb Award (Division 6, APA) and the Exemplar Award (Animal Behavior Society). She served as associate editor of the *Journal of Comparative*

*Psychology* (2011–2016). She has also received numerous teaching awards.

Dr. Pepperberg has served on the editorial boards of seven different journals, on the National Science Foundation Animal Behavior grant review panel, on the board of directors for the Eastern Psychological Association and *Thinking Animals*, on the Science Advisory Board for the Austrian Science Fund, the review panel for the biannual conference on The Evolution of Language (*Evolang*) five times, the executive council for the American Ornithologists' Union (AOU), and as representative to the Ornithological Council for both the AOU and the Cooper Society. She has chaired the Public Affairs Committee and ran a legislative email alert system for the Animal Behavior Society. She is a foreign affiliate of the British Psychological Society.

Dr. Pepperberg has authored or coauthored over 60 peer-reviewed publications and over 80 book chapters, commentaries, and reviews and has given over 60 keynote or plenary addresses, over 370 invited professional presentations, and almost 80 contributed talks and posters. She also speaks several times each year at non-academic outreach events. She is the author of *The Alex Studies* (Harvard University Press) and *Alex & Me* (HarperCollins), co-edited *Animal Cognition in Nature* (Academic Press), and is an associate editor for the *APA Handbook of Comparative Psychology* (2017). She is a yearly contributor to *The Edge* annual question. With respect to the popular press, her research has been featured in articles in venues as diverse as the *New York Times*, *Die Welt*, *National Geographic*, the *Wall Street Journal*, *Audubon Magazine*, and the *New Yorker*; in television programs such as *Scientific American Frontiers*, *Discovery*, *BBC Nature*, and *Nova Science Now*; and in various outlets in Europe and Japan. After the parrot Alex died in 2007, his obituary was published worldwide, including in *The Economist*, the *New York Times*, *Der Spiegel*, and *Time* magazine.

**Irene M. Pepperberg**, PhD, is a research associate and lecturer in the Department of Psychology at Harvard. She has served a 6-year term as associate editor for the *Journal of Comparative Psychology* (2011–2016). Her interests are in animal cognition and communication, particularly with respect to Grey parrots. She specializes in training parrots to learn to use English speech to communicate referentially with humans and then using this communication code to examine their cognitive processes.

## Definition

Ivan Pavlov (1849–1936) was a Russian physiologist, Nobel Prize winner, and well known in the field of psychology for his research on classical conditioning.

## Introduction

Ivan Petrovich Pavlov, a Russian physiologist, is well known in the field of psychology for his research on classical conditioning. Pavlov began his career by becoming a skilled surgeon, which permitted him to perform many experiments on the digestive system of animals without severely

inhibiting normal functioning. These experiments allowed him to understand the process of classical conditioning, as well as contribute to the fields of abnormal and personality psychology. Today, several ongoing areas of research have their roots in Pavlov's research, and Pavlov has become immortalized in textbooks from a variety of fields in psychology.

## Early Life and Career

Ivan Petrovich Pavlov (1849–1936) was born in Ryazan, Russia, on September 26, 1849. His father, Peter (1823–1899), was an orthodox priest and his mother, Varvara (1826–1890), stayed at home with Ivan and his ten siblings. Although he was born into a religious family, attended religious instruction, and enrolled in the seminary, Ivan Pavlov soon redirected his attention to studying chemistry and physiology at the University of St. Petersburg (Furedy 2003). Even though his father withdrew financial support when Pavlov decided to pursue studies in the natural sciences, Pavlov continued and completed his degree in animal physiology. Under the mentorship of Elias de Cyon, a skilled surgeon, Pavlov became an expert in surgical procedures and skilled with the scalpel. During this time, Pavlov focused his research on the heart and digestive systems (Fields 2006).

After graduating with honors, he went on to the Imperial Academy of Medical Surgery in 1875 (Fields 2006). Controversy related to Cyon led Pavlov to leave the Academy and enroll in the Veterinary Institute of St. Petersburg where his focus remained on the digestive system.

Pavlov soon traveled to Germany to begin his work with an expert in digestion, Rudolf Heidenhain. While in Germany, he continued to improve his surgical skills and developed his theory of nervism while working on his dissertation (Palmer 2000). This theory posits that nerves control the majority of bodily functions.

Pavlov married a friend of author Fyodor Dostoyevsky, Seraphima Vasilievna Karchevskaya (1855–1947) in May of 1881. They went on to have four sons and a daughter, though they lost one son during childhood (Fields 2006).

Pavlov earned his medical doctoral degree in 1883 from the University of St. Petersburg. In 1884, Pavlov returned to Germany to begin his work with Karl Ludwig who was a cardiovascular physiologist (Fields 2006). With Ludwig and Heidenhand as collaborators, Pavlov created his own laboratory where he continued his studies on nervism (Palmes 2000). It was under Heidenhand's tutelage and having studied Nikolai Eck's shunt creation that Pavlov implemented the use of pouches and the creation of gastric and pancreatic fistulas in animals that enabled him to study organs without worrying about environmental or surgical procedures interfering with normal functioning (Palmes 2000).

Pavlov believed that stress influenced physiological reactions of animals and that this led to interference with his results. He disagreed with the practice of vivisection or surgery on live animals and instead championed the policy of surgically altering animals under anesthesia before conducting research so the animal would experience less stress and behave more typically than if in distress. He continued to train young scientists to perform procedures to limit the stress and pain animals experienced so that neither influenced the outcomes of their research (Kopaladze 2000).

In 1891, he was invited to be the director of the physiology department at the Institute of Experimental Medicine. In 1895, he simultaneously held this position and a professor of physiology appointment at the Imperial Military-Medical Academy in St. Petersburg (Asratyan 1953). It was at the Institute of Experimental Medicine that Pavlov conducted his research on the digestive system that eventually led to his Nobel Prize award (Marks 2004). In 1935, he presided over the XV International Congress of Physiological Sciences in Moscow. Six months later, in February of 1936, Pavlov died of pneumonia. To honor him, his research laboratory was preserved as a museum (Cambiaghi and Sacchetti 2015).

## Pavlov's Contributions to Psychology

Though Pavlov was awarded a Nobel Prize for research on the digestive system, he is most well known in the psychology field for his research on

classical conditioning. Pavlov studied the digestive system in dogs by conducting surgical procedures, which allowed him and his colleagues to measure saliva and other digestive secretions in healthy, awake animals. It was during these experiments that Pavlov realized the dogs would start salivating in response to other stimuli besides their food. After careful experimentation, Pavlov concluded that the salivating to a non-food stimulus was a conditioned reflex, which is a reflex that occurs in response to a particular stimulus only after that stimulus has been paired with another stimulus which has previously elicited the same reflex without conditioning. In Pavlov's lab, the unconditioned stimulus was the dogs' food, which naturally caused salivation (unconditioned reflex). The conditioning process happened when research assistants brought the dogs their food, as both assistants and food repeatedly appeared at the same time. Eventually, the dogs would salivate upon seeing the research assistants (conditioned stimulus), even when no food was present (conditioned response) (Fields 2006). This is the process of classical conditioning, as it commonly referred to in psychology, also known as the conditioned reflex.

In many accounts of how Pavlov discovered or studied classical conditioning, a bell is repeatedly paired with food and eventually becomes a conditioned stimulus so that the bell alone would cause the dogs to salivate. The accuracy of the accounts where Pavlov used a bell has sometimes been questioned as false; however, other historians have found that Pavlov used many different stimuli, including lights, sounds, and objects, including a bell (Jarius and Wildemann 2015).

Prior to Pavlov's experiments on conditioning, it was not well understood why a dog would salivate even before food was placed in its mouth. As Pavlov began to manipulate the type of food and conditions in which food was presented to his research subjects, he termed this response "psychic secretion" because it was the dogs' brains and nervous systems that caused the salivation response (Todes 1997). These experiments demonstrated that the dogs anticipated being able to eat the food and were even able to generalize different stimuli and environmental conditions as indicating that food would soon be

given to them, a very adaptive trait. Adaptability to changing environmental conditions allows for a better chance of survival and Pavlov recognized that his subjects' rapid habituation and dishabituation to environmental stimuli allowed for such adaptability (Marks 2004).

Though Pavlov's early research was strictly physiological, Pavlov had an increasing interest in mental phenomena which he felt could not be dealt with scientifically unless they were measured in terms of physiological quantities. Pavlov was interested in the mind's subjective nature and was not a strict behaviorist as he has often been labeled. The study of associative learning, one of the major research fields in psychology today, began with Pavlov's systematic experiments on dogs' salivation in 1901 (Gray 1999). Pavlov was strict in his direction of the laboratory's experimental methods, ensuring that all research assistants and colleagues followed rigid methodical protocols in order to reduce error and confounding variables.

After many years of careful experimentation and hundreds of publications on the topic, Pavlov published *Conditioned Reflexes* in 1926. The now world-famous term "conditioned reflex" likely resulted from an error in translation. The Russian term that Pavlov used is argued by some to be more accurately translated as "conditional reflex" and has a slightly different meaning (Todes 2014). The term "conditional" implies that the resulting action or reflex is not an innate response to a stimulus in the traditional sense of the word "reflex." One criticism of Pavlov's work is that he attributed all associative learning to cortical areas of the brain, despite this being false because some animals without a cortex are capable of associative learning (Todes 2014).

Pavlov is most commonly associated with classical conditioning, but he also made several other contributions to the field of psychology. The many experiments Pavlov conducted with the dogs over an extended period of time allowed Pavlov to see that there was a wide range of individual differences among the dogs, which he emphasized as needing to be considered when designing experiments. Pavlov even noted that the results of

experiments were influenced by the temperament or personality of each dog, demonstrating the biological basis of personality (Dewsbury 1997). Additionally, the area of abnormal psychology became of interest to Pavlov after several of his dogs developed neurotic behavior. In one circumstance, extensive flooding of Pavlov's laboratory left several dogs traumatized and behaving abnormally (Fields 2006), while in another circumstance, a sensory experiment caused abnormal behavior (Windholz 1997). Pavlov attributed the dogs' abnormal behavior to the sensory overload that was experienced in both events and attempted to apply his observations to the field of human psychoses and psychotherapy. The Russian method of psychiatric patients being treated in unstimulating, quiet rooms was developed based on Pavlov's view that excessive inhibition and abnormal behavior was a protective mechanism and due to overstimulation (Horsley 2012). Under trained psychiatrists, Pavlov studied human psychoses, specifically schizophrenia, through interviews and observation (Windholz 1997). Other psychology topics that Pavlov addressed were aging, language, and problem solving (Horsley 2012; Windholz 1997).

## **Pavlov's Legacy: Scientific Contributions, Contemporary Research, and Political Influence**

### **Scientific Contributions**

Pavlov's legacy includes his contributions to the development of medicine, physiology, and pathology of higher nervous system activity. His research on digestive functions and diseases forms the foundation for modern scientific medicine (Pivovarov and Shok 2016). He was a pioneer on work with vascular surgery and the use of portocaval shunts. His work on digestion made him a household name in Russia. He was also among the first scientists to reach recognition outside of the Russian scientific community, and he became highly regarded worldwide (Palmer 2000). For example, in the 1950s the term "Pavlovian response" was commonly used to describe

the automatic, reflex-like reactions of the Chinese soldiers (Furedy 2003). In addition to his research contributions, he also was ahead of his time by describing ethical guidelines when working with live animal subjects (Kopaladze 2000).

Pavlov is remembered today for his numerous achievements and awards during his outstanding scientific career. In 1901, he was elected a corresponding member of the Russia Academy of Science. In 1904, he won the Nobel Prize in medicine for his research on digestion. Numerous honorary memberships in scientific societies were bestowed to him, notably at Cambridge University in 1912. In addition, he was awarded the Order of Legion of Honor by the Medical Academy in Paris in 1915 (Palmes 2000).

### Contemporary Research

Classical conditioning is the foundation of the modern science of learning. Pavlov's most important conceptual contribution to science was in the field of experimental psychology. The "dog-and-bell scenario" is described in all major textbooks and has become "common knowledge" (Jarius and Wildemann 2015). Even today, classical conditioning is referred to as Pavlovian Conditioning and a Pavlovian Society advocates for guiding principles related to understanding behavior derived from Pavlov's work (Furedy 2003).

Many psychological researchers over the years have utilized Pavlov's work on learning and conditioning in their own scientific studies. Pavlovian concepts such as reinforcement, extinction, and generalization have become critical components of modern psychology (Windholz 1997). There have been a wide variety of topics studied utilizing classical conditioning including conditioning sexual responses in humans (Rachman and Hodgson 1968), contextual fear conditioning in animals (Rudy et al. 2004), and using fear conditioning and extinction to understanding anxiety disorders and PTSD (VanElzakker et al. 2014). Understanding the development and treatment of phobias (and later anxiety) have been extensively studied using Pavlovian techniques since initially proposed by Watson and Rayner (1920). In anxiety disorders, such as PTSD, the

symptoms fail to extinguish after repeated exposure, or reminders of past events, even decades later. Fear conditioning and extinction research paradigms have proven extremely relevant to understanding and possibly preventing anxiety disorders and PTSD (VanElzakker et al. 2014).

Recently Pavlov's ideas on the causal and functional approaches to behavior (Pavlov 1927) have expanded to include ecological and cognitive perspectives.

Ecological perspective – This perspective explores the ways in which conditioning is important for an animal to survive and reproduce. Researchers are concerned with how Pavlovian signaling of biologically important events allows animals to respond adaptively (Hollis 1997). An example of this line of research in the blue gourami fish is a demonstrated competitive advantage during male-male competition, including a phenomenon where winners keep winning and losers keep losing in competition. Classically conditioned males tended to win both the first and second fights, whereas losers lost again (Hollis et al. 1995). Similarly, anti-predator defense research in the ecological perspective has produced many well-known studies such as species specific defense reactions (SSDR) (Bolles 1970) elicited in rats (freezing in defense of danger) and the behavior systems theory, which organizes behavior into categories such as feeding, mating, and avoiding predators (Timberlake 1994). Research on courtship and reproduction in birds has found that classically conditioned mating cues increase reproductive success (Hollis et al. 1997). Other areas in the Ecological Perspective that Pavlov has influenced include research on food recognition, psychoneuroimmunology, and drug tolerance and addiction (Hollis 1997). For example, Siegel (2005) built upon earlier findings linking classical conditioning to drug (i.e., heroin) overdose, symptoms of withdrawal, and environmental cues related to addiction. Overall, this research perspective supports the theory that classical conditioning can influence behaviors crucial for survival, such as knowing what to eat. It also provides an understanding of how classical conditioning can help with behavior change

problems, such as breaking addiction, in everyday life (Hollis 1997).

**Cognitive perspective** – Starting in the latter half of the twentieth century, a paradigm shift in psychology led researchers to focus on cognitive processes including exploring the mental mechanisms that occur during classical conditioning (Hollis 1997). This transition was not widely accepted by behavioral researchers. Even today, the Modern Pavlovian Society does not condone the shift to a cognitive paradigm due to limitations of the concept of representation and the computer metaphor often employed in cognitive theory (Furedy 2003).

Other researchers have used Pavlov's work on classical conditioning as a starting point from which to explore topics such as how the mind organizes the relationship between the conditioned stimulus and the unconditioned stimulus and the different kinds of responses that occur following the stimuli (Hollis 1997). In a summary of this work, Hollis (1997) describes studies ranging from the description of cellular neural mechanisms responsible for classical conditioning to examining differences in conditioning across taxa. One well-known theory to be proposed based on Pavlov's work by Rescorla and Wagner (1972) explained the effect of conditioning which appears to be based on the strength of the association between the stimuli.

All of the above examples demonstrate that Pavlov's work has been influential in many areas of psychology.

### Political Influence

Well-known for his discoveries in the laboratory, Pavlov used his position as a respected Russian scientist to openly and publicly advocate for human rights (Pivovarov and Shok 2016; Windholz 1997). He became a national hero for criticizing the Russian government for their oppression and infringement on academic and religious freedom (Todes 2014). Due to his worldwide notoriety, he was one of the few public and independent voices in the Soviet political system. Pavlov's frustration with limited research resources and funding led him to deliver incendiary speeches and write numerous letters to

Russian officials criticizing the regime. Government officials tolerated his vocal dissent due to his prominence. They eventually supported Pavlov's research requests and his efforts to enhance the reputation of the Russian contributions to the scientific community while maintaining a level of disdain for Pavlov himself (Pivovarov and Shok 2016). Pavlov was a voice for science, even when it was potentially costly for his livelihood and freedom.

### Summary

A Nobel Prize-winning physiologist and prominent researcher, Ivan Petrovich Pavlov is a figure central to the history of psychology and the conception of classical conditioning. Though his experiments with the iconic dogs salivating at a ringing bell were not as simple or serendipitous as many textbook portrayals, Pavlov's contributions to the understanding of behavior shaped by classical conditioning are essential to modern psychology research and practice. Pavlov's surgical skills, experimental practices, and interest in behavior all shaped the research for which Pavlov became famous. Pavlov's legacy continues to live on through his immortalization in the historical narrative of psychology and through the numerous areas of contemporary research that he inspired.

## J Bruce Overmier

J. Bruce Overmier

University of Minnesota, Minneapolis, MN, USA

J(ames) Bruce Overmier, born in New York and trained as a chemist at Kenyon College (1960), stumbled into psychology in 1960 based on hearing lectures at Denison University by Joseph Brady on the “Executive Monkey” (1958) and by William Mayer (Mayer 1959) on the Korean POWs and their “giving up” under random stresses and rewards. These had significant impact and the themes re-emerge in his research career. He was educated in psychology at Bowling Green State University (Ohio, MA 1962) under mentor John R Schuck and at University of Pennsylvania for PhD (1965) under mentor Richard L. Solomon. He also did postdoctoral work in England in zoology and comparative physiology. Overmier taught at the University of Minnesota for 49 years publishing some 200 papers, chapters, books, and reference CDs over that career. The underlying research was funded virtually continuously by NSF, NIMH, and NICHD and involved fish, rats, pigeons, dogs, and humans. Overmier’s research is surveyed briefly in two general domains: basic behavioral and behavioral neuroscience, each roughly broken into several contributing bodies of work in comparative psychology each with a dozen or more publications. The cited publications below were often co-authored by

Overmier with his PhD students and postdoctoral fellows who have gone on to distinguished careers and to whom he is genuinely indebted.

Overmier’s basic behavioral research involves three interrelated lines. The first line of research associated with Overmier is that of “Learned Helplessness” that grew out of his interests in the POW experiences. This work began with a paper that discovered the proactive interfering effects of moderate trauma experience on subsequent learning to escape aversive events (Overmier and Seligman 1967). In that paper, the authors describe the empirical phenomenon of learned helplessness and its dimensions, and they introduced the theory of learned helplessness as a cognitive state of expectations of the uselessness of trying to cope. Overmier (1968) also showed that it impaired future avoidance as well as escape, and began an experiment with Seligman and Maier (1967, see their footnote) that identified the uncontrollability of the initial trauma as a critical causal feature. Few doubted the empirical phenomenon (but see Lawry et al. 1978); but the cognitive construct was savaged by strict behaviorists (e.g., Levis 1976). Learned helplessness gained recognition as a proposed model for depression and for PTSD. Over the years, the construct and its causal features were modified (Abramson et al. 1978), and the unitary dimensionality of learned helplessness came to be seen as at least bi-dimensional (Overmier and Wielkiewicz 1983) involving separately the loss of control (general learned helplessness) and the

absence of prediction (general learned irrelevance) (Dess and Overmier 1989). Eventually, Overmier came to argue that the “learned helplessness” construct was an artifact of the early design and selected normal reference condition (Overmier 1998), and that failure of coping was the default condition of trauma and that opportunities to predict or control aversive events reduced the experienced trauma allowing for more effective future coping. This stimulated new research by Maier (Maier and Watkins 2010) that yielded new insights and physiological mechanisms of stress and trauma (see overview, LoLordo and Overmier 2011).

A second line of related research involved questions of the nature of avoidance learning and how pure Pavlovian conditioning (i.e., involving no instrumental motor contingencies) could come to convey to CS the power to evoke separately learned responses. This does not sound very novel – even then – because M. May (1948) had reported an experiment that claimed to show this phenomenon of CSs evoking escape responses. But Overmier observed a procedural flaw in the May experiment that had transformed the supposed escape trained response into actual avoidance responses, and an experiment (Ehrman and Overmier 1976) confirmed that the May report erred. This was important because the May experiment was the foundation for the explanation of avoidance learning promulgated by Kimble in his textbook (1961) and widely accepted. In fact, fear CSs could only evoke previously trained avoidance responses. Overmier and associates then widely explored the properties of both aversive and appetitive CSs in controlling instrumental responses learned under appetitive or aversive conditions (e.g., Overmier and Lawry 1979). This line of research goes under different rubrics – “transfer of control,” “Pavlovian-instrumental transfer” (PiT) – but continues today in many laboratories because of the importance of these phenomena in understanding so-called cognitive capacities (Holden and Overmier 2010; Overmier 2010).

A third line sprang from the second line in the form of a question about what features of evoked central states functioned to control the responses

in the transfer of control experiments. The “obvious” and common initial answer taken from O.H. Mowrer was that a conditioned motivational state had properties in common with the motivational state – fear – controlling the learned avoidance response, and this commonality led to a generalized response. But then, one might ask, are fears of different aversive events different (Overmier et al. 1971)? And the answer is “yes,” and this difference can come to selectively evoke different instrumental responses (Trapold and Overmier 1972); they interpreted this as revealing that, in addition to any motivational properties, the discriminative stimulus or CS evoked central states also had cues that acted to guide responses. This led to a line of research infelicitously called the “differential outcomes effect” in which it was demonstrated that the learning discriminated choice responses is speeded, better remembered, and resistant to disruption – say by some drug or distractor (Overmier et al. 1999) – if each response is followed by a distinctive or “differential” outcome. This finding, so simple, has had many applied outcomes in teaching children, learning disabled, and senile patient populations things that they could not otherwise even learn (Hochhalter et al. 2000; Maki-Kahn et al. 1995). Other experiments have demonstrated the neural correlates of these differential outcomes and the evocation of the different choice responses (Browning et al. 2011; Mok et al. 2009). One of the more surprising results of using the differential outcomes procedure is that, while making the choice, it seems that the chooser does not even remember the discriminative cue but only the expected outcome (Holden and Overmier 2015).

Overmier’s behavioral neuroscience domain research is basically divisible into two lines. In each of these, the research also harked back to issues and/or methods used in the basic behavioral work, but the focus was on the neuroscience mechanisms. The first of these behavioral neuroscience lines involved analysis of the role of the telencephalon (forebrain) of the teleost. Early experiments in the 1930s had lesioned or even extirpated the telencephalon in fish and reported virtually no effects! Such reports are stunning given the importance of the forebrain in “higher”

vertebrates. Because he had been working on avoidance and limbic structures were critical for avoidance learning in mammals, he and fellow students simply assumed this to be true for fish as well, and they demonstrated exactly that (Hainsworth et al. 1967). Overmier followed up on this finding with a series of other researches seeking to identify just what element or form of learning was disrupted by the forebrain ablation (escape: no; classical conditioning: no, integration of the two: yes, etc., Flood et al. 1976) and other assessments of forebrain function (Overmier and Gross 1974; Overmier and Papini 1985).

A second line of behavioral neuroscience research harks back to those Executive Monkeys who he learned died of gastric ulcers as a result of their avoidance challenge. But the research on this did not begin until the 1980s (Murison et al. 1986), wherein he and Norwegian colleagues began to take up this old problem. Using a model ulcer induction procedure, they identified many experiential stress factors that influenced the precipitation, induction, and persistence of gastric ulcers and linked them to underlying physiological factors (e.g., Murison and Overmier 1993). Of course, “causes” of ulcers became an unpopular topic with the discovery of *helicobacter pylori* and the claim that it accounted for the epidemiology of ulcers. But a recent review (Overmier and Murison 2013) concluded that the *helicobacter* emphasis was much overdone and that psychological factors as demonstrated in Overmier and Murison’s research program are significant factors in the ulcer profile of individuals.

Beyond these lines of research, he has coauthored papers that contributed basic data foundational to things like the Opponent Process theory (Church et al. 1966), understanding somatic disability (Overmier 2002), the surprising importance of assumedly trivial methodological factors (Lyte et al. 2005; Meyers-Manor and Overmier 2015), and international reference works (Overmier and Overmier 2004).

Overmier has won many awards for his research (e.g., D. O. Hebb Distinguished Scientific Contribution Award in Behavioral Neuroscience and Comparative Psychology, 2015), for his

contribution to psychological societies (American Psychological Association Award for Distinguished Service to Psychological Science, 2005), and for his teaching (e.g., American Psychological Association BEA Outstanding Graduate Teaching of Psychology as a Core STEM Discipline Award, 2014). He has received three honorary doctorates. He has served as president of five national psychology organizations and of the International Union of Psychological Science, and as an officer or board member of several other national and international psychology organizations (e.g., International Council of Science, Paris).

Throughout his career, Overmier has argued for basic animal researches as models that can give fundamental insights into the health status – mental and physical – of humans (e.g., Overmier and Patterson 1988). His research career has reflected this with his basic researches building towards accounts of the human condition and challenges.

## J.E.R. Staddon

Kenneth M. Steele  
Department of Psychology, Appalachian State  
University, Boone, NC, USA

## Personal History

John Eric Rayner Staddon was born on March 19, 1937, in Grayshott, Hampshire, England, a village about 74 km (46 miles) southwest of London. He was the first child of Leonard John (Jack) Staddon and Dulce Norine Rayner

Staddon. The parents had met when Jack Staddon was serving in the military in Rangoon. The Staddons, including his grandmother, Irene Florence Rayner, moved to London a year later and settled finally in Cricklewood, an area of north-west London. Staddon’s earliest memories center around World War II and the bombing of London. His father was on active duty and his mother was working outside of the home. Staddon was raised during this time by his grandmother.

Staddon attended Burgess Hill, a progressive school that permitted much student freedom. Staddon remembered he was able to avoid math and that every boy had a knife. The 2 fun years of Burgess Hill did not prepare Staddon well for the *eleven plus* exams that determined the next educational step. Staddon did well enough to be accepted at St. Marylebone Grammar School, although he was to need additional tutoring in math. About this time, Staddon began to develop a serious interest in biology. He had several aquaria and had purchased a used microscope. Staddon’s record of *A-level* passes did not guarantee acceptance at a top-level research university. He matriculated at Battersea Polytechnic, which was accredited to grant degrees from the University of London. The school was not a good match, and Staddon discovered that he could transfer into the psychology track at University College London (UCL) if he did well enough on a standardized test. Staddon enjoyed UCL; he skipped a lot of lectures and tutorials and became involved with the student newspaper as a movie and art reviewer.

Staddon’s father had moved to Northern Rhodesia for work. The family joined him there, including John Staddon in the middle of his UCL career. Staddon found a job working for a program to study disease (e.g., malaria and bilharzia) and nutrition in the region. Staddon worked as a lab and physician’s assistant on the project. Staddon lived there from 1957 to 1959 and then returned to England to finish his final year at UCL.

Staddon passed his exams at UCL, but not at the level to be accepted for postgraduate work at a research university. Nor did he have research lab experience that might have led to a stronger personal recommendation. Staddon decided to try his

luck in North America. He found ads at the UCL Psychology Department for research assistantships at Kansas State University, McMaster University in Hamilton, Ontario, Canada, and Hollins College in Roanoke, VA. He received a similar offer from all three schools. He chose Hollins because it would be warmer and less flat.

Staddon arrived at Hollins in 1960 to discover that it comprised only women students at the undergraduate level. Another shock was the American educational system, which required regular class attendance and featured frequent testing. Staddon was to meet Robert Bolles, who introduced Staddon to Murray Sidman's (1960) *Tactics of Scientific Research*. Sidman was a student of B. F. Skinner. The book explained Skinner's methodology, which was focused on the performance of individual subjects. This approach was to be used by Staddon throughout his career. A second memorable event of Staddon's time at Hollins was that he met his first wife, Nada Ballator. Hollins did not offer a Ph.D. degree, and Staddon applied to three programs, receiving an acceptance at Harvard University.

The Harvard Psychology Department was located in the enormous basement of Memorial Hall. At one end were the pigeon labs and the office of B. F. Skinner. The other end contained the office of S. S. "Smitty" Stevens, famous psychophysicist and methodologist. The combined location of faculty, graduate students, and labs on the same floor led to extensive interactions among the labs. Staddon took several courses at the Massachusetts Institute of Technology where he learned to think about feedback systems from a computational viewpoint.

Richard Herrnstein was the supervisor of Staddon's dissertation, B. F. Skinner having retired from active laboratory work. Research activity in the operant conditioning lab was focused on Herrnstein's *matching law*, the principle that relative (or proportional) response rate would match relative reinforcement rate in a two-choice conditioning task. Staddon, however, was interested in a different topic, the influence of timing on responding. Pigeons can adapt to a *Fixed-interval 30-s* schedule, in which food is

available only after a period of 30 s and will not respond for a period of 10 to 15 s from the beginning of the interval. However, if the task is to pause 10 s before making the next response, then pigeons find this to be a very difficult task. Staddon investigated whether providing feedback signals of too early or late responses would improve performance. The results were mixed and showed that pigeons did not use feedback in a human-like manner.

Staddon's first job was at the University of Toronto in Canada, and it did not proceed as anticipated. The winters were interminable, and the intellectual temperature in the department was cool, too. The major animal learning theorist in the department was a neo-Hullian, Abram Amsel, famous for his *frustration theory*. Frustration was a drive-like condition that was supposed to be elicited by the nonoccurrence of an expected reward. Staddon developed a more parsimonious explanation of the effect and presented it to the Amsel group. Predictably, it did not produce a welcome reaction. (See Staddon and Innis 1969, for the analysis.)

Staddon began to look about for a new position and saw an ad for a position at Duke University. His interview was in January and it was sunny and balmy in Durham, NC. The animal learning atmosphere was warmer, too. The senior learning person was Norman Guttman, a former student of Skinner. Staddon took the job and remained at Duke for the rest of his career. He retired in 2007 as a James B. Duke Professor of Psychology and Neuroscience but has remained intellectually active since then.

Interested readers should consult Innis (2008) and Staddon's autobiography (Staddon 2016) for additional details of his career.

## Brief Overview of Staddon's Work

Staddon's most cited paper is the replication of Skinner's (1948) superstition experiment (Staddon and Simmelhag 1971). Skinner reported when food was presented to a hungry pigeon on a periodic basis independent of the pigeon's behavior, then an operant conditioning effect was

produced. Whatever behavior occurred closest in time to presentation of the food was repeated such that it was likely to reoccur close in time to the next food presentation. The effects were interpreted to indicate the power of temporal contiguity of a reinforcer to stamp in a response even when there was no causal connection between the two events. It is important to note that almost no data is presented in the article. Instead, Skinner presents verbal descriptions and his conclusions.

Staddon and Simmelhag (1971) replicated the basic procedure of Skinner (1948) of presenting response-independent food, with important additions. They developed a coding system to record the different activities by the pigeons and the temporal location of the activities during the interfood interval. Their results showed that the behavior closest in time to food in the initial sessions (e.g., head in the feeder) was often displaced abruptly by another activity (e.g., pecking the wall near the feeder) in later sessions. The result was a direct contradiction of the account that temporal contiguity of response and reinforcer alone can explain the emergence or persistence of behavior.

Staddon and Simmelhag noted that the other activities (dubbed *interim activities*) occurred also in a reliable sequence. The observation led to the question of the cause of the regular occurrence of those activities since they are both unnecessary for and temporally distant from food reinforcement. Their insight was that a hungry animal was not in search of food alone. Instead, it had several requirements (food, water, avoidance of predators) that had to be met. The problem for the animal was *allocation of behaviors*, when is the best time to do what activity. A period of low food probability is a good time to engage in other activities. This issue of the problem of behavior allocation was to occupy Staddon for several years.

Staddon (1979) pursued the issue formally (mathematically) by recasting operant conditioning as a behavior allocation issue. Reinforcement schedules restrict an organism's access to one activity by requiring it to engage in a second activity. The problem for the animal is how to balance the preferred levels of both activities (the *free behavior point*) given the

constraints imposed by the contingency. Staddon used both geometrical and algebraic analyses in his *minimum distance* model to suggest that the final performance is one that brings the mix of behaviors closest to the mix of the free behavior point. Staddon (1980) edited a volume of contributions that showed the allocation issue ranged from plants to human behavior in the suburbs.

### A Simple Example of Staddon's Modeling Approach: Habituation

Staddon's (2001) current method of investigation is to create formal models of the manner in which behavior changes in time. These models are black box models. No attempt is made to justify these models by appealing to current views of the nervous system or cognitive metaphors, such as *expectancy*. The approach follows the Turing test argument. You have an adequate model of thinking when a reasonable questioner cannot discriminate between a machine and a human being. The goal of development of these models is *parsimony*. The more simple the mechanism then, the more widely it may be used in nature.

An example of Staddon's approach can be seen in a simplified description of his analysis of habituation (Staddon 1993). *Habituation* is the waning of the strength of a response with repeated elicitation by a specific stimulus. The speed of habituation increases when the frequency of presentation of stimulus is increased. There is recovery from habituation when the stimulus is not presented for some time period. Habituation represents a dynamic case of behavior change in time.

Figure 1 shows a diagram of a basic habituation unit (Staddon 1993). The relevant equations are

$$V(t+1) = aV(t) + (1-a)X(t), 0 < a < 1 \quad (1)$$

$$V_0 = X - V, \text{ if } V_0 > \theta \quad (2)$$

The model operates like a digital clock, with each increment in  $t$  the equivalent of a tick of the clock. The figure indicates two effects

J.E.R. Staddon,

**Fig. 1** Diagram of habituation unit adapted from Staddon (1993). See text for details

induced by the stimulus (“ $X$ ”): an excitatory component where stimulus strength directly increases response strength and an inhibitory component (“ $V$ ”) that suppresses responding. Equation 1 describes the effect of the current trial on  $V$  for the next tick of the clock. When  $X > 0$ , then inhibition will increase and  $aV(t)$  is described as a *leaky integrator*. The leaky integrator sums (integrates) prior experience with the stimulus, but the inhibitory effect ( $V$ ) will wane (leak) with time according to the value of the constant,  $a$ , with smaller values producing greater leakage in  $V$ . The occurrence and strength of the response are predicted in Eq. 2 by the mathematical difference between current excitatory and inhibitory values (i.e.,  $X - V$ ) if it exceeds a threshold ( $\theta$ ). If the stimulus is absent ( $X = 0$ ), then  $V(t + 1)$  will decrease according to the size of  $aV(t)$ .

The question of interest to Staddon is whether this mathematical equation will reproduce the basic dynamic effects of habituation, as described above. If the model does so, then it has passed a kind of Turing test, an equivalency of the behavior of the model and an animal. The advantage of the model is that the behavior has been described without a commitment to a specific theoretical account. The basic unit may then be combined with other habituation units in series or parallel to describe more complex behaviors (Staddon 1993, 2005; Staddon and Higa 1996, 1999).

Current learning theories tend to fall into a small number of approaches, using mainly cognitive or neuroscience metaphors. Staddon’s emphasis on the descriptive powers of mathematical models offers a third, distinctive approach.

## Jane Goodall

Malin K. Lilley and Maria Zapetis  
The University of Southern Mississippi,  
Hattiesburg, MS, USA

### Definition

Conservation leader and humanitarian who made several ground breaking discoveries on chimpanzee behavior in Tanzania and is a current advocate for animal welfare around the world.

### Introduction

In a time when humans were the only species in the world to make tools, naming conventions of study subjects were restricted to numbers, and women in science were few and far between, Jane Goodall stepped onto African soil and changed the way we thought about animals, the environment, and ourselves. Goodall spent over 20 years researching the chimpanzees in Gombe to discover groundbreaking facts about their previously elusive behavior, and, perhaps even more alluring to the public, their social relationships, individual personalities, and emotions. Rich with experience and full of courage and compassion, Goodall's life has become the topic of numerous articles, novels, children's books, movies, television shows, and conversations. To this day, Goodall is absorbed in her conservation work, traveling most of the year in order to spread a message of conservation and peace to all citizens of the world (Jane Goodall Institute 2016). Goodall has become a legend in the study of chimpanzee behavior and a symbol of conservation because she has dedicated her life, professional and personal, to these causes.

### Personal Life

On April 3, 1934, Valerie Jane Morris-Goodall was born in London. Her mother, Vanne Morris-Goodall, was a novelist and her father, Mortimer

Herbert Morris-Goodall, was a businessman (Jane Goodall Institute 2016). When Mortimer enlisted in the military during WWII and no longer lived at home, Vanne served as a strong, independent female role model for Jane and her younger sister Judy. When Jane was 12, her parents divorced and Jane continued to live with her mother's family in the countryside, where they had moved during the war (Goodall and Berman 1999).

Living in the countryside allowed Jane to be immersed in nature from a young age. There are many anecdotes of Jane exploring the outdoors and observing animals, such as chickens and the family dog. Jane showed an interest in animal welfare from a young age: she took care of earthworms and did not want to hurt dragonflies. Goodall's favorite toy as a child was a stuffed chimpanzee that was given to her by her father (Jane Goodall Institute 2016). Other early influences in Jane's life included her grandmother who was another strong female role model, and a number of books, especially the story of Dr. Doolittle and Tarzan (Jane Goodall Institute 2016). These books sparked an interest in studying the wildlife of Africa, one of her long-term goals.

Throughout her childhood, Jane continued to demonstrate her love of wildlife by starting "The Alligator Club," in which Jane, Judy, and their two friends learned about wildlife together and held small events. Goodall was a good student, but preferred to be outdoors with animals rather than inside a classroom. However, she did complete her secondary education and went on to train as a secretary. Throughout her childhood and young adult life, Goodall reflected on the nature of humans, often wondering how they could sometimes be so intelligent and yet be responsible for atrocities such as the Holocaust (Goodall and Berman 1999). Goodall's curiosity with the nature of aggression and human self-awareness would later be reflected in her reports on violent and peaceful aspects of chimpanzee societies and her work as a United Nations Messenger of Peace (Jane Goodall Institute 2016).

After Jane trained as a secretary, she went to work at the University of Oxford Registrar's Office and then a film studio in London, but these jobs were not particularly fulfilling. When one of her friends from school invited Jane to visit

her father's farm in Kenya, she was ecstatic, as it was her dream to visit Africa. She moved back home to work as a waitress in order to save money and boarded a Kenya-bound ship in 1957. Jane loved being in the very place she read about in her favorite stories as a child, and sought employment to extend her stay (Goodall and Berman 1999).

Jane was hired as a secretary for the paleoanthropologist, Louis Leakey, who was the curator of the Coryndon Museum in Nairobi. Jane accompanied Leakey and his family on fossil digs in the Olduvai Gorge. There, Jane was able to be a part of the search for the missing links in the evolution of *Homo sapiens*. Leakey spoke of his desire to research the behavior of wild chimpanzees because ancient human behavior was not fossilized, and the closest option for looking at prehistoric human behavior was to observe the closely related chimpanzees. Eventually Jane vocalized her desire to observe chimpanzees, which led Leakey to make logistical arrangements and secure funding from the Wilkie Foundation and National Geographic Society for Jane's expedition (Lindsey 1999).

Vanne Morris-Goodall accompanied Jane to what is now the field station at Gombe National Park, Tanzania. The mother-daughter pair proved to be resilient in the foreign environment and persevered through a period of sickness and fever. Vanne set up a medical clinic at their research camp, which helped to establish a rapport with the locals and demonstrate that Jane and her mother were there to help. After several years of fieldwork and a few new discoveries, Jane secured continued funding for the project. In 1962, her sponsor (the National Geographic Society) sent Hugo van Lawick to photograph and film Jane and the chimpanzees in Gombe. By 1965, she was married to van Lawick and had earned her PhD from the University of Cambridge with Robert Hinde as her advisor. Goodall is one of just a handful of people who had been granted a PhD without first earning a bachelor's degree (Jane Goodall Institute 2016).

By 1967, Goodall gave birth to a son (Hugo Eric Louis van Lawick, aka Grub) and had created the Gombe Stream Research Centre with funding from the National Geographic Society. Graduate

and undergraduate students from the United States, Europe, and Tanzania flocked to the new center to conduct field research on chimpanzees. As the new center's Scientific Director, Goodall encouraged a cooperative, tight-knit community, where researchers shared data, exchanged information, and presented their findings in open, casual settings. As the number of researchers in the center expanded, so did their species of interest; some began studying other primate species' behavior as well (Greene 2008). The additional man-power enabled Goodall to spend most of her time writing research findings, proposals, advising students, attending to administrative duties of the center, and raising Grub. As a new mother, Goodall spent as much time as possible with her son in Gombe. Many of Goodall's mothering techniques were actually learned from observing the chimpanzee Flo raise her own children. Goodall followed Flo's affectionate example of child rearing, even though it was considered unorthodox at the time (Pratt 1997). At the age of nine, Grub returned to England for schooling and lived with his extended family there.

As the findings of the Gombe Stream Research Centre were disseminated and the number of researchers grew, Goodall began to give more lectures and talks overseas. She traveled as a visiting professor of Psychiatry and Human Behavior at Stanford University from 1970 to 1975 and published her first book, *In The Shadow of Man* (1971). Goodall divorced Hugo in 1974 and later remarried Derek Bryceson, director of Tanzania's national parks, in 1975 (Goodall and Berman 1999). The same year, four foreign students in the research center were abducted by armed revolutionary soldiers, and as a precaution, no foreign students were allowed back until 1989. In the intermediary, day-to-day operations of the research center relied almost entirely on the African researchers and staff. Goodall created the Jane Goodall Institute for Wildlife Research Education and Conservation to financially sustain research in Gombe and returned from her position in Stanford, enjoying her life with the small, all-African research group once more. However, even the duration of her own visits to Gombe were restricted. Goodall and Derek lived happily

together until he succumbed to cancer in 1980, which Goodall has described as an extremely painful time in her life (Goodall and Berman 1999).

Goodall returned to Gombe to heal and experienced a moment of clarity after a thunderstorm in the forest (Goodall and Berman 1999). She set out to compile her findings of many years in Gombe into a single book that would both contribute to the field scientifically and be easily understood by the public. After 6 years she published *The Chimpanzees of Gombe* (1986), which distinguished Goodall as a leader in the field of primatology and chimpanzee behavior. To celebrate, Drs. Goodall and Heltne (Chicago Academy of Sciences) organized a conference on the topic of chimpanzees that would subsequently change the direction of Goodall's career, and begin her voyage as one of the modern era's most famous advocates of animal welfare and conservation.

## Research

When Goodall began her research in Gombe Stream Chimpanzee Reserve on Lake Tanganyika in 1960, very little was known about wild chimpanzee behavior. Goodall's mentor and advocate for the study, Louis Leakey, was a paleoanthropologist who believed that studying such a close relative of the human species would provide insight into the evolutionary origins of human behavior (Lindsey 1999).

Research in the forests of Tanzania was not an easy task. Upon Goodall's arrival at Gombe, the chimpanzees were elusive and avoided close proximity to her. Everyday Goodall would climb trees, travel through the thorny undergrowth, carefully avoid other wild animals, and endure long spans of time without food and water in order to search for, and observe the resident chimpanzees of Gombe. Sometimes Goodall would even sleep near the chimpanzees' nest site so that she could wake up with them the next morning (Goodall 1963). After several months, a chimpanzee Goodall previously named David Greybeard allowed Goodall to approach him. This was an

invaluable step of progress for Goodall's research, as it enabled closer observation of the rest of the chimps and their gradual desensitization to Goodall's presence.

Goodall visually identified all 89 chimpanzees who inhabited the territory at Gombe (Goodall 1986). Unlike most other scientists at the time, Goodall gave each research subject a name, acknowledged that they had unique personalities, and immersed herself in their environment (Jane Goodall Institute 2016). Leakey saw Goodall's lack of formal training as an advantage because it meant that she did not bring some of the preconceptions and biases someone with a formal education would possess (Jane Goodall Institute 2016). However, her education level, anthropomorphic tendencies, and gender caused Goodall's observations, interpretations, and abilities as a researcher to be the target of doubt and criticism by many others in the research community. Regardless, Goodall made many remarkable discoveries concerning chimpanzee communication, social structure, relationships, ranging patterns, foraging tendencies, hunting, aggression, affiliative behavior, dominance, sexual behavior, territoriality, tool use, and social awareness, among other cognitive abilities (Goodall 1986).

Chimpanzee relationships provided Goodall with context for their social interactions. She categorized relationships as friendly, unfriendly, or sexual and found that the social bond between mother and offspring was the strongest in her population (Goodall 1986). Goodall learned that young chimpanzees stayed with their mothers for up to 7 years after birth, helped to care for siblings, and formed long-lasting bonds with members of their social group. Although the chimpanzees had a larger social unit that was relatively stable over time, individuals or smaller family units were often found apart from the larger group, which constituted a "fission-fusion" society (Goodall 1963). The males of each social group had their own dominance hierarchy, and while there was also a dominant individual among female chimps, she did not maintain her dominance in the male hierarchy (Goodall 1963).

As Gombe's chimpanzee social unit began to fragment, Goodall was able to document the

aggressive nature of chimpanzees. The two new communities established territorial boundaries within the larger territory they had previously shared. The males of a group patrolled the boundaries of their territory together. Goodall reported on how several members of one group would isolate and attack a member of the neighboring group, killing the individual or inflicting fatal wounds in a sort of primitive warfare (Goodall and Berman 1999). Goodall also witnessed several cases of infanticide, where a mother-daughter pair killed newborns of other mothers within the same social group. These observations contributed to the discussion on whether aggressive tendencies of humans and chimpanzees are learned or inherited.

However, Goodall assured that the vivid displays of chimpanzee violence did not occur more frequently than peaceful interactions, and continued to report on the chimpanzees' caring and cooperative nature (Goodall 1986). The chimpanzees engaged in close physical contact upon greeting one another with gestures that resembled human hugs, holding hands, and kisses. Goodall learned that chimpanzee mothers had different mothering styles, just like humans. Some chimpanzee mothers were very protective, while others allowed their young more freedom, sometimes ignoring them altogether (Goodall 1963). The chimps spent long periods of time grooming one another, tickling each other, and laughing. Goodall described how chimpanzees would engage in seemingly selfless acts to help fellow group members, including one instance when an adult male adopted a young orphaned chimp, which was a very atypical social arrangement (Goodall and Berman 1999).

In her descriptions of chimpanzee foraging and hunting behavior, Goodall revealed that chimpanzees were not primarily vegetarians and fruit eaters as previously thought (Goodall 1986). Chimpanzees ate mammals, including bushpigs, rats, and mice and often shared their kills with their group mates. They also ate birds, termites, and a variety of vegetation such as leaves, blossoms, stems, seeds, and fruit (Jane Goodall Institute 2016). Even more remarkable than the finding that chimpanzees ate meat were Goodall's

observations of the chimpanzees making and using tools to extract termites from mounds. Goodall was the first to document their process of modifying a twig, dipping it into the insects' underground tunnels, and extracting the twig covered in termites to eat, which was termed "termite-fishing" (Goodall 1970). At first, many scientists did not believe that Goodall had actually witnessed tool use and tool modification in another species. However, later photo documentation of the process verified to the world that humans were no longer defined solely by their ability to use tools. The most famous quote on this matter came from Louis Leakey himself when he said, "Now we must redefine man, redefine tool, or accept chimpanzees as humans!" (Jane Goodall Institute 2016). Over time, Goodall witnessed the chimpanzees using leaves as tools for other tasks, such as soaking up water, cleaning themselves, and wiping wounds (Lindsey 1999).

In addition, Goodall discovered that chimpanzees had a rich vocal and nonvocal system of communication. Although the vocalizations of the chimpanzees did not form a complete language, Goodall documented approximately 30 distinct calls (Goodall and Berman 1999). After spending considerable time with each chimpanzee, she was able to identify individuals based on their vocal characteristics and learned the meaning of several vocalizations from context. She believed that these signals could also be used while conveying psychological and emotional state and never doubted the chimp's ability to feel emotions that other scientists reserved for humans (Goodall 1986; Goodall and Bekoff 2002). She witnessed the chimpanzees building the nests they slept in at night, playing in the rain, and watched them mourn the death of a family member.

Goodall began to publish her novel findings and was featured in a National Geographic television program, which resulted in her international celebrity status (Lindsey 1999). This positively affected the Jane Goodall Institute and ultimately the Gombe Stream Research team. Continued funding permits the Tanzanian researchers, accompanied by students from all over the world, to continue Goodall's work by studying narrow

research topics in great depth (Jane Goodall Institute 2016). Today, the Gombe Stream Research Centre hosts many researchers whose study topics include health, genetics, mother-infant relationships, maternal stress, personality, social networks, cooperation, aggression, aging, menopause, and conservation using spatial mapping technology (de Donno et al. 2015). This research center has over 55 years of continuous data on over 300 chimpanzees from three populations and has been part of over 400 publications. Goodall has especially inspired many women to pursue primatology, conservation, and wildlife research. Additional research is conducted at Jane Goodall Institute's Tchimpounga Chimpanzee Rehabilitation Center to better understand many aspects of chimpanzee health and behavior and ultimately to provide tools to better protect them.

## Conservation Work

The 1986 "Understanding Chimpanzees" conference in Chicago was a transformative experience for Goodall (Goodall et al. 2009). Chimpanzee experts from around the world presented their research, but underlying the entire conference were conversations on the increasingly threatened state of chimpanzees in the wild (Goodall 2001). A session on conservation reviewed the unsustainable deforestation occurring across the chimpanzees' range, the increased consumption of bushmeat, the sale of infant chimps into captivity, and their poor living conditions once there (Goodall 2001; Goodall et al. 2009). After the conference, Goodall felt she could no longer prioritize fieldwork while her voice and celebrity status could help the chimpanzees' many dire plights (Goodall et al. 2009; Peterson 2006). The end of the conference marked the founding of the Committee for the Conservation and Care of Chimpanzees (CCCC) by 30 conference attendees at the top of their field, and Goodall reborn as an animal welfare advocate (Goodall 2001).

Goodall began actively traveling as a lecturer and activist an average of 300 days a year (Jane Goodall Institute 2016). She gave presentations to

schools and corporations, attended conferences, fundraisers and meetings, solicited funds, met with politicians, and attempted to convince environmental group leaders to take a more active role in conservation efforts (Goodall 2001). Although the Jane Goodall Institute was still being used to support wild chimpanzee research in Gombe, its mission began to expand with the creation of the CCCC, and it gradually became recognized as a leader in the conservation nonprofit sector (Goodall 2001; Pratt 1997). Today the institute supports programs in conservation science, research, advocacy, protecting chimpanzees and other great apes, public awareness, environmental education, healthy habitats, and has initiated two successful community-based outreach programs: Roots & Shoots and TACARE.

Roots & Shoots is a grassroots service program that aims to foster respect, compassion, and understanding in young people, as they work to increase the wellbeing of the human community, animal welfare, and the local environment (Goodall 2002). The program's name was symbolic in that it described the strong, foundational aspect of roots that were everywhere, and the indomitable nature of a young tree that seems weak at first but is capable of growing up to break through brick in order to reach the sun (Goodall 2002; Peterson 2006). The grassroots program that began with 12 children in Dar es Salaam now has Roots & Shoots clubs in nearly 100 countries with over 5,800 reported conservation and service projects (Jane Goodall Institute 2017). The program seeks to empower youth and build strong, introspective, purposeful, empathetic, adaptable, optimistic, inspirational leaders who think critically and work well as a team, and maintains that every individual can make a difference. While initially designed and implemented for students from elementary school to university, there are now Roots & Shoots members of all ages, all around the world (Goodall 2002; Jane Goodall Institute 2017).

The Lake Tanganyika Catchment Reforestation and Education (TACARE) Program was specifically targeted towards individuals who lived in the same areas as wild chimpanzees (Lindsey 1999). By offering courses in

sustainable natural resource management, TACARE empowers locals to protect the land, plant nurseries, and become financially independent. In this way, TACARE addresses the socioeconomic needs of people in the local community, as well as chimpanzees' need to have accessible habitat, and the environment's need to recover. The program addresses humanitarian concerns such as community development, encourages forestry initiatives such as tree planting, teaches sustainable agricultural practices, initiates health projects such as family planning and reproductive education, and introduces the Roots & Shoots program to local youth (Lindsey 1999).

Goodall has improved the lives of many human and animal communities around the world. Most notably, she has created multiple sanctuaries for chimpanzees orphaned due to the bushmeat trade (Goodall and Berman 1999; Lindsey 1999). In addition, the Jane Goodall Institute has helped improve the quality of care for animals in low-income zoos, particularly in developing countries. The ChimpanZoo Project called for much-needed behavioral analysis of captive chimpanzee populations. With this, Goodall aimed to compare wild chimpanzee behaviors with behavioral reports from their captive counterparts. By discovering the needs of captive chimps, such as larger enclosures, social interaction, and environmental enrichment, ChimpanZoo continues to help improve chimpanzee exhibits all over the world (Lindsey 1999).

After touring a medical research laboratory in 1987, Goodall created a list of minimum requirements needed for the wellbeing of research chimpanzees. While these requests were initially dismissed, Goodall's basic requirements (i.e., larger cages and social interaction) were slowly incorporated into the industry (Goodall 2001; Peterson 2006). Goodall continued to persist, and as of 2015, the National Institute of Health (NIH) announced the retirement of all biomedical research chimps. Today, all chimpanzee medical experimentation has ended, and any remaining chimps in labs are being transported to chimp sanctuaries or retirement centers (Golden 2017). While Goodall is especially passionate about improving the treatment of chimpanzees (and

other animals) in captivity, she does not condone extremist activist groups, as she feels that polar opposition does not facilitate a conversation for a sustainable future. While violence may have evolved as part of our nature, Goodall believes we can (and should) choose to solve problems peacefully (Goodall and Berman 1999). Instead of pointing blame, Goodall focuses on hope.

Goodall has authored books conveying a more humane view of wildlife for children (*The Chimpanzee Family Book*) and argues for a deeper connection between people and the natural world (*The Ten Trusts*). She believes that understanding more about nature enables us to care, and it is that caring that ultimately enables us to take action (Goodall and Bekoff 2002). *The Ten Trusts* (2002) calls for a more compassionate attitude towards animals from scientists and the general public. The "trusts" ask us to acknowledge that (1) we are part of the animal world (and that we are not the only animals with emotions such as fear, joy, embarrassment, anger, love, sadness, or grief), (2) there is a value in every being (animal or plant) which deserves our respect, (3) that we can learn from many species and (4) should teach a love and respect for nature at a young age, (5) aim for a smaller carbon footprint, (6) work towards reversing extinction by reducing pollution and man-made noise, (7) refrain from using harmful methods to study animals, (8) take action, (9) help conservationists, and (10) remember to have hope.

In other novels, Goodall explores the idea of hope in the modern world. She details the capacity of humans to rescue many endangered species from near extinction (*Hope for the Animals and Their World, Reason for Hope*). Although Goodall was initially skeptical of captivity, she now embraces the immense benefits that captive facilities, their associated breeding programs, and teams of researchers can have on animals, especially those who are critically endangered or extinct in the wild. Goodall lists her reasons for hope as "(1) the human brain; (2) the resilience of nature; (3) the energy and enthusiasm that is found or can be kindled among young people worldwide; and (4) the indomitable human spirit" (Goodall and Berman 1999, p. 233).

During her lectures and invited talks, Goodall is known for presenting her “symbols of hope,” such as a California condor feather, which she carries with a permit (Goodall et al. 2009). She also travels with a leaf from a very resilient old tree, another feather from a peregrine falcon thought to be locally extinct for 100 years, and a paw print cast of one of the last wild black-footed ferrets believed to exist in 1986. These items not only carry symbolic importance for Goodall, but are used in her speeches to convey that many species can come off the endangered, and even extinct, species lists. She believes that too often we are told about species dying, but we do not celebrate the successful ventures of breeding programs and recovery efforts with the same vigor (Goodall et al. 2009). Currently, Goodall offers a class about conservation through an online education platform (MasterClass 2017). Her syllabus includes lessons on animal behavior and intelligence, anthropogenic effects on the environment, conservation biology, tips on presentations, how to advocate without hostility, and Goodall’s reasons for hope in the next generation of conservationists.

## Conclusion

The research that Goodall began in 1960 has snowballed into a global research effort to understand and protect primates and their environment. With discoveries including meat-eating, tool-making, termite-fishing, child-rearing, aggression, and affiliative behavior, Goodall began a legacy of research that continues today, and has taught the world about our closest evolutionary cousins. She has authored several books, from scientific to autobiographical, such as the best-seller, *In the Shadow of Man* (1971). Much like her career, her book titles have shifted focus to encourage readers to stay hopeful and active in the face of animal extinctions and the changing world. As she calls out to the public to rise in action, she also calls out to scientists: Goodall believes that there is still a great deal of work to do towards implementing compassionate research methods and improving the welfare of animals in

captivity, as well as the habitats of their wild counterparts (Goodall and Bekoff 2002).

Goodall’s continued efforts to improve the quality of life for all animals, communities, and environments have earned her more than 60 awards and recognitions (Doak 2015). Among them are the San Diego Zoological Society’s Gold Medal of Conservation, the J. Paul Getty Wildlife Conservation Prize, the Animal Welfare Institute Schweitzer medal, the National Geographic Society Centennial Award, and the Kyoto Prize for Basic Sciences, which is the Japanese equivalent to the Swedish Nobel Prize. In 2002, she was recognized as a United Nations Messenger of Peace and was granted the title of Dame of the British Empire by Queen Elizabeth II in 2003 (Welty 2011).

Although her conservation work has taken her far away from her beloved chimps, and Gombe, Goodall’s peaceful-yet-powerful actions, rational outspoken mentality, and ethical integrity are an inspiration for so many around the world. The Jane Goodall Institute has blossomed in recent years with programs to monitor and protect habitats that are critical to the chimpanzees, educate local communities, raise awareness, promote sustainable consciousness, and encourage grassroots efforts among youth. Through her lectures, classes, advocacy, and institution, she has impacted the environment and future generations of conservationists to come.

## Jealousy

Jennifer Vonk

Department of Psychology, Oakland University,  
Rochester, MI, USA

## Synonyms

Envy; Possessiveness

## Definition

A desire for attention, affection, or resources given to competitors/rivals within the context of close social relationships.

## Introduction

Jealousy is one of the secondary emotions along with shame, embarrassment, guilt, and pride (Miller and Leary 1992). It is sometimes confused with envy, but envy is generally defined as the desire for an object, whereas jealousy can be defined as the desire for affection or attention directed at another (Cohen-Charash 2009). Unlike the other secondary emotions, jealousy and envy do not involve the evaluative component that involves reflection on how one is perceived by others (Morris et al. 2008). For example, embarrassment stems from the feeling

that one has done something to encourage derision from others. The secondary emotions are tied to the emergence of self-awareness in humans and are expressed for the first time within the last half of the second year of life in typically developed humans (Lewis et al. 1989). This is the same age at which mirror self-recognition is evidenced and personal pronouns are used. For this reason, and because of the absence of strong evidence for self-awareness in nonhuman animals, it has been of interest to determine whether animals may experience secondary emotions, such as jealousy (Bekoff 2002).

Jealousy may emerge earlier in humans – as early as 9 months (Hart 2016) – making it more likely that it might be shared more widely within the animal kingdom compared to late-emerging emotions such as embarrassment and pride. However, it is extremely difficult to test the experience of emotions in nonverbal species. For that reason, researchers must rely on observations of behavioral manifestations that may be linked to human experiences of jealousy. In addition, there is recent neurophysiological evidence that supports the claim that some species may experience something akin to human jealousy.

## Adaptive Value

Emotions such as jealousy may serve an adaptive function in motivating individuals to compete for resources such as mates. Jealousy may motivate others to prevent rivals from monopolizing or interfering with important social relationships – with mates, siblings, and potential allies (Chung and Harris 2018; Harris and Prouvost 2014). It might be presumed that jealousy is more likely to be experienced in highly social species; however, it may be adaptive for any species that compete with siblings for a parent's attention, or with rivals for mates. Thus far, jealousy has not been explored in relatively less social species, and in fact, its study has been restricted to animals in human care such as animal companions (primarily domestic dogs) and species closely related to humans, such as nonhuman primates.

## Pet Owner Surveys

Researchers have asked pet owners to report on emotions that they believe they have observed in their animal companions. Although people frequently describe their pets as behaving jealously anecdotally (Hötzel et al. 2019; Mathes and Deuger 1982; Mitchell and Hamm 1997; Morris et al. 2008), those reports generally follow an immediate precipitating event rather than being indicative of a longstanding abstract emotional response to existing relationships. Morris et al. (2008) found that owners reported jealousy at higher rates compared to the other secondary emotions. Among dog owners, jealousy was most commonly attributed to dogs when the owner was affectionate toward another human, in particular, their romantic partner. The more attached people were to their animal companions, the more they attributed emotions to them. Jealousy was attributed to dogs and cats at high levels in another study as well (Su et al. 2018). A drawback of the survey report method is that it cannot speak to the underlying emotional experience of the animal and results may reveal more about the circumstances in which humans are likely to ascribe a familiar human emotion to animals. That is, animal caregiver reports may reflect little more than the human tendency for anthropomorphism. Nonetheless, the species that jealousy has been most commonly ascribed to and the contexts in which it is presumed to occur may inform viable directions for further research.

It is possible that behaviors appearing to reflect underlying feelings of jealousy are instead responses to the perceived loss of a resource. In some dog breeds, guarding behavior, which may mimic jealous reactions, may have been selected for over generations and may not reflect the same underlying emotional motivation. Dogs may also be reacting to the loss of reinforcement for positive behaviors. Dogs that behave aggressively to a stranger that is receiving attention from their owner may be experiencing fear or anger rather than jealousy. The owners might preferentially interpret the behavior as motivated by jealousy because such emotions reflect the bond between human and companion animal.

## Experimental Work

Experimental work could tease apart dogs' responses to attention that is redirected to another from their owners compared to other humans with whom they have no attachment or weak attachment. Prato-Previde et al. (2018a, b) did not find that dogs in their studies differentiated between caregiver and stranger interactions with identical objects. These findings might cast some doubt on the likelihood that the dogs' response could be conceptualized as human-like jealousy. To further understand the motivations underlying behaviors appearing to reflect jealousy, researchers have also investigated the response of dogs when their caregiver directs attention to different objects. For example, Abdai et al. (2018) demonstrated that dogs exhibited more jealous-like behaviors when caregivers attended to other social partners rather than to inanimate objects. Harris and Prouvost (2014) found that dogs engaged in more aggressive and attention-seeking behavior when their caregiver was paying attention to a toy dog that moved and barked compared to when they paid attention to a book or other inanimate object. Furthermore, researchers compared these apparent jealous reactions in cases where attention was simply withdrawn but not directed to another recipient, and failed to find an increase in ostensive jealous behaviors in such cases. Cook et al. (2018) additionally found greater amygdala activation (indicating emotional reactivity) when dogs observed their owners providing food to fake dogs compared to when they simply placed dog in a bucket. Unfortunately, the availability of food for the dog subjects was not carefully matched and the dogs may have been responding to the food rather than their owner's attention in this study. In addition, there was no control condition where the fake dog did not receive food from the subject dog's owner (Vonk 2018).

Moreover, some researchers have questioned whether dogs really perceive fake toy dogs are being animate, and therefore as legitimate rivals for affection (Prato-Previde et al. 2018a, b). Fake dogs may elicit more attention from the subject dogs because they are strange and unfamiliar objects that fail to behave as expected.

Furthermore, dogs in Prato-Previde and colleagues' studies did not try to interfere with the caregivers' interactions with the fake dogs or to redirect the caregivers' attention to themselves. These results cast further doubt on the legitimacy of the general paradigm.

## Neurobiology of Emotion

Despite its shortcomings, Cook et al.' (2018) study was notable for investigating amygdala activation in addition to observing the behavioral response of the dogs. Jealousy has been linked to activation in the amygdala in humans (Harmon-Jones et al. 2009), making the finding of activation in dogs while observing their owners interacting with fake dogs intriguing. Rilling et al. (2004) observed similar activation in the amygdala and related brain areas of male rhesus macaques that observed their mates interacting with other males. Rilling et al.'s study is also one of a few examining animal's reactions in the context of relationships with conspecifics rather than humans. Thus far, such studies have been conducted only with nonhuman primates. For example, Maninger et al. (2017) observed monogamous male coppery Titi monkeys using functional imaging to examine cerebral glucose metabolism. They also measured hormones involved in mate guarding, such as testosterone, cortisol, oxytocin, and vasopressin. They allowed the male titi monkeys to observe their own mates and unfamiliar females positioned next to unfamiliar males. The males looked longer when their mates versus the unfamiliar females were paired with the stranger males. Potentially more compelling was the finding that neurological and hormonal changes in the expected direction coincided with these behavioral differences leading Maninger and colleagues to speculate that these physiological changes could be identified as markers of jealousy in nonhuman primates. These changes might be adaptive in maintaining reproductive units.

Jealousy may be experienced outside of the reproductive context in nonhuman primates as well. For example, Webb et al. (2020) observed

a group of captive chimpanzees when new members were introduced into their social group. Male chimpanzees were more likely than females to intervene when close male associates interacted with novel group members of the same sex. The negative reactions were the most pronounced for relationships that were described as especially close. These strong reactions to male-male dyads clearly do not serve to maintain reproductive bonds, but may serve to protect and enhance coalitionary relationships, which enhance fitness in a different way. The sex differences are interesting as it is male chimpanzees that hunt and patrol together and form alliances to defend their own group and attack males of rival groups (Mitani and Watts 2005).

In conclusion, jealousy may be adaptive in a range of competitive contexts, primarily within close social relationships and therefore is assumed to be widespread among social animals. However, it is unlikely to be restricted to group-living animals as it may allow the young of any mother-reared animals to compete for resources. Thus far, studies have been conducted only with some domestic companion animals and primates and few paradigms have been used leaving this a rich topic for further study.

## Synonyms

Charles Darwin; Lamarkism; Traits

## Definition

Evolution is the phenomenon of informative hidden potentialities. It is the improvement within the genetic characteristics of biological populations over additional generations. This is the method of evolution that has given rise

to diverseness at each level of biological establishment, as well as the amount of species, individual organisms, and molecules.

## Introduction

Lamarck a French naturalist, biologist, and an early pitch of the thought that evolution (ancestry with moderation) occurred and began in accordance with natural laws. Lamarck, however, is remembered today mainly in relatedness with his now displaced theory of heredity, the “inheritance of acquired traits.”

In a broad surrounding, Lamarckism remains of use when examining the evolution of cultures and ideas. It is generally held in terms of some religious views on “karma” and inheritance of sin, and remains relevant to some scale for bacteria and microorganisms. Lamarck was also one of the first to use the term *biology* in its recent perception, and he coined the term invertebrates.

## Biography

Lamarck was born in Bazentin-le-Petit, Picardie, into an impoverished family (hence the title of *chevalier*, knight).

Lamarck served in the army before fetching interested in natural antiquity and writing a multi-volume flora of France. This caught the attention of Georges-Louis Leclerc, Comte de Buffon who arranged for him to be appointed to the Museum National d'Histoire Naturelle in Paris, France. After years working on plants, Lamarck was scheduled curator of invertebrates. He also began a series of public lectures.

Earlier 1800, Lamarck was an essentialist who whispered species were rigid; however, after working on the mollusks of the Paris Basin, he build up assured that transmutation of species, or change in the construction of species, appeared over time. He set out to develop a description, which he outlined in his 1809 work, “*Philosophie Zoologique*.” Lamarck urbanized two laws to describe evolution: the “*law of use and disuse*”

and the “*law of inheritance of acquired characteristics*.”

Lamarck saw spontaneous generation as being ongoing, with the simple organisms thus created being transmuted over time becoming more complex and closer to some notional idea of perfection. He thus believed in a teleological process where organisms became more perfect as they evolved.

Lamarck founded a school of French *Transformationism* which included Etienne Geoffroy Saint-Hilaire, and which corresponded with a radical British school of comparative anatomy based at the University of Edinburgh, which embraced the surgeon Robert Knox and the explorer Robert Edmund Grant. Professor Robert Jameson wrote an anonymous paper in 1826 approving “Mr. Lamarck” for justification how the superior animals had “evolved” from the “easiest worms,” this was the first utilize of the word “evolved” in a current wisdom. As a young student, Charles Darwin was trained by Grant and worked on marine creatures with him.

During his life span, Lamarck became controversial; his disapproval of the paleontologist Georges Cuvier’s anti-evolutionary stance won him no friends.

Lamarck married three, perhaps four, times. His first wedding was to his courtesan from 1777, Marie Delaporte, the mother of his first six children, whom he married in 1792 on her death-bed. He remarried in 1795 to Charlotte, but she died in 1797. Lamarck wedded his third wife, Julie Mallet, in 1798. She died in 1819. Rumor exists of a fourth wife and widow but no written proof exists of her. Lamarck slowly turned blind.

On 28 December 1829, Lamarck passed away in Paris.

## Lamarckism

Lamarckian progression is a theory put additional based on the heritability of acquired features by Lamarck, the once widely received design that an organism can pass on characteristics that it acquired all the way through its life span to its offspring.

Lamarck suggested that individual efforts during the lifetime of the organisms were the main mechanism operating species to adaptation, as they supposedly would acquire adaptive changes and pass them on to offspring. While extremely admire during the near the beginning nineteenth century as an account for the complication observed in living systems, after publication of Charles Darwin’s theory of natural selection, the importance of separate efforts in the generation of adaptation was significantly reduced. Later, Mendelian genetics replaced the concept of inheritance of acquired traits, ultimately leading to the progress of the modern evolutionary synthesis, and the general deportation of the Lamarckian theory of evolution in biology.

## Lamarck’s Theory

The evolution of giraffe necks is frequently used as the example in simplification of Lamarckism.

Erasmus Darwin wrote *Zoonomia* suggesting “that all warm-blooded animals have arisen from one living filament,” and “with the power of acquiring new parts” between 1794 and 1796 in response to stimuli, with each round of “improvements” being inherited by consecutive generations. Subsequently Lamarck proposed in his “*Philosophie Zoologique*” of 1809 the theory that characteristics that were “needed” were diminished during the lifetime of an organism were then passed on to the offspring. He saw this resulting in the evolution of species in a continuous chain of development towards higher forms.

Lamarck based his theory on two inspections, in his day examined to be generally true:

1. Individuals lose characteristics they do not necessary and develop characteristics that are useful.
2. Individuals inherit the traits of their ancestors.

With this in mind, Lamarck evolved two laws:

1. **Law of use and disuse.** *In each animal which has not proceed the limit of its development, a more frequent and continual use of any organ gradually strengthens, develops, and enlarges*

*that organ, and gives it a power proportional to the span of time it has been so used; while the durable disuse of any organ imperceptibly weakens and deteriorates it, and progressively diminishes its functional capacity, until it finally disappears.*

2. **Inheritance of acquired traits.** *All the acquisitions or depletion wrought by nature on individuals, through the impact of the environment in which their race has long been placed, and hence through the consequences of the major use or permanent disuse of any organ; all these are preserved by reproduction to the new individuals which arise, provided that the acquired modifications are common to both sexes, or at least to the discrete which produce the young.*

Examples of Lamarckism included:

- Giraffes stretching their necks to get to leaves high in trees strengthen and slowly lengthen their necks. These giraffes have offspring with moderately longer necks (also known as “soft inheritance”).
- A blacksmith, during his work, strengthens the muscles in his arms. His sons will have analogous muscular growth when they adult.

In essence, a change in the environment brings about change in “needs,” resulting in change in behavior, bringing change in organ usage and development, bringing change in form over time – and thus the gradual transmutation of the species.

Although such a theory strength describe the notable diversity of species and the first law is generally true, the major argue against Lamarckism is that experiments basically do not hold up the second law – simply “acquired traits” do not appear in any significant logic to be inherited. For example, a human child must learn how to propel a ball even though his or her parents learned the same feat when they were children.

The dissension that instinct in animals is confirmation for hereditary knowledge is generally regarded within science as false. Such behaviors are more possibly passed on through a mechanism

called the Baldwin effect. Lamarck’s theories acquired preliminary acceptance because the mechanisms of Mendelian inheritance were not explained after Lamarck’s death, until later in the nineteenth century.

## Proponent

The “*Vestiges of the Natural History of Creation*,” written by Robert Chambers and published certainly in 1844 in England, suggested a theory modeled after Lamarckism, causing political debate for its radicalism and unorthodoxy, but exciting popular interest and paving the way for Darwin.

In the 1920s, experiments by Paul Kammerer on amphibians, certainly the midwife toad, emerged to find attestation supporting Lamarckism but were disgraced as having been falsified. In *The Case of the Midwife toad*, Arthur Koestler suspected that the specimens had been faked by a Nazi sympathizer to disgrace capacities Kammerer for his political views.

In the 1920s, Harvard University researcher William McDougall studied the potentialities of rats to correctly solve mazes. He claimed that offspring of rats that had learned the maze were able to race it faster. The first rats would get it wrong an average of 165 times before being able to run it perfectly each time, but after a few generations, it was down to 20. McDougall credited this to several variety of Lamarckian evolutionary method.

When Trofim Lysenko assisted Lysenkoism, a shape of Lamarckism was released in the Soviet Union of the 1930s, which complemented the ideological opposition of Joseph Stalin to genetics. This unscientific agricultural policy was extinct blamed for crop failures and famine.

Steele et al. (1998) produced some indirect corroboration for somatic transfer of antibody genes into sex cells via reverse transcription.

Homologous DNA sequences from VDJ – regions of parent mice – were created in germ cells and then their offspring. However, there has been no definitive experiment.

Neo-Lamarckism is a theory of inheritance based on an alleviation and addition of Lamarckism, necessary to prolonging the principle that genetic changes can be modulated and absorbed by ecological factors.

## Lamarckism and Single-Celled Organisms

While there is no confirmation with respect to higher organisms for Lamarckism – that is, there is no proof that acquired changes are genetically transmitted – a number of scientists quarrel that it can be perceived among microorganisms, with influenced changes inherited in the middle of bacteria and protozoans (Cairns 1998).

John Cairns, Stefan Miller, and Julie Overbaugh suggested in a publication in *Nature* in 1988 that some *E.coli* mutations could extend in a Lamarckian approach (Cairns et al. 1988). The class took a mutated strain of *E. coli* that was impotent to consume the sugar lactose and placed it in an environment where lactose was the only food source. They detected over time that mutations occurred within the colony at a rate that recommended the bacteria were overcoming their handicap by modifying their own genes. Cairns, among others, dubbed the process adaptive mutagenesis.

If bacteria that had overcome their individual incapability to get through lactose passed on this “learned” trait to future generations, it could be disagreed as a form of Lamarckism, though Cairns later select to distance himself from such a situation. More ordinarily, it might be observed as a form of ontogenic evolution.

There have been a few researches into Lamarckism and prions. A category of researchers, for example, discovered that in yeast cells containing a particular prion protein Sup35, the yeast were able to acquire new genetic material, some of which gave them new capabilities such as resistance to a particular herbicide. When the researchers mated the yeast cells with cells not containing the prion, the trait reappeared in some of the resulting offspring, indicating that some information indeed was

passed throughout, though whether or not the information is genetic is debatable: trace prion amounts in the cells may be passed to their offspring, giving the appearance of a new genetic trait where there is none (Cohen 2004).

Finally, there is growing evidence that cells can activate low-fidelity DNA polymerases in times of stress to induce mutations. While this does not directly converse advantage to the organism on the organismal level, it makes sensation at the gene-evolution level. While the succession of novel genetic traits is unsystematic, and assortment residues Darwinian, the dynamic process of identifying the necessary to mutate is considered to be Lamarckian.

## Lamarckism and Inheritance of Acquired Artistic and Spiritual Characteristics

Jean Molino (2000) has suggested that Lamarckian evolution may be accurately appealed to cultural evolution. This was also formerly suggested by Peter Medawar (1959) and Conrad Waddington (1961).

Likewise, religions generally cohere to the view of the inheritance of acquired spiritual traits. That is, there is an observation that manners in one’s life concern one’s spirit and that such passes down to one’s lineage in the form of religious merit or demerit. This is the outlook that the “sins of the fathers, when they have not been properly expiated, are passed on and lead to evil consequences for subsequent generation” (Wilson 1991). The set of guidelines of karma, common to many Eastern religions, as well as the inheritance of sin in several Western religions, reflects this point of view.

## Conclusion

The process and development of organic evolution is slow and gradual. The second part of Lamarck’s machinery involved the inheritance of acquired traits for evolution. He trusted that traits changed or acquired over an individual’s life span could be permitted to its offspring.

Darwin's theory has been assisted by a lot of confirmation. Lamarck's "Theory of Inheritance of Acquired Characteristics" (second law) has been not proved. The other way that Lamarck's theory has been confirmed incorrect is the study of genetics. Darwin knew that traits are approved, but he never understood how they are accomplishing. Lamarck is most excellent notorious for his theory of "Inheritance of Acquired Characteristics," first presented in 1801 (Darwin's first book dealing with natural selection was published in 1859): If an organism changes during life in order to adapt to its environment, those changes are passed on to its progeny. Lamarck's contribution to evolutionary theory consisted of the first truly cohesive theory of biological evolution, in which an alchemical complexifying force drove organisms up a ladder of complexity, and a second environmental force converted them to local environments through use and disuse of characteristics. Lamarck and Darwin's theories were extremely different but they were also much related. They both thought that organisms changed. They thought these changes could be very helpful and could help them endure. Lamarck and Darwin's theories are both the same and dissimilar in several ways.

## Johannes Müller

Roger K. Thomas  
Department of Psychology, University of  
Georgia, Athens, GA, USA

## Introduction

Johannes Peter Müller, 1801–1858

Johannes Peter Müller was born on July 14, 1801 in Coblenz, Germany, an ancient city in middle Germany. Some well-respected historians spell his surname “Mueller” (Young 1990). Müller died on April 28, 1858 in Berlin. Among numerous outstanding achievements during his career, he published several books including the eight books between 1833 and 1840 that comprised his *Handbuch der Physiologie des Menschen*. The *Handbuch* established Müller as the most renowned physiologist of his time. He made important discoveries in physiology, improved upon the discoveries of others, and mentored some of the most important physiologists/physicists of the nineteenth century. In his later years, he devoted most of his effort to the study of single-celled marine animals.

Born the son of a shoemaker, Müller was initially destined to have a career in leather work, but his success in the gymnasium (high school) resulted in his father being persuaded to allow him to enroll in the University of Bonn in 1819. In 1822, Müller earned a medical degree based on a study of animal movement, especially arthropods. Müller then spent a year and a half at the University of Berlin where his principal mentor was Carl Rudolphi, Germany's most eminent anatomist. Müller returned to Bonn initially as a lecturer but eventually as professor. Rudolphi died in 1832. In 1833 Müller was invited to succeed him at the University of Berlin. Müller remained at the University of Berlin until his death from cause unknown; some suggested suicide. Müller spent much of his adult life suffering from depression largely attributed to overwork and to constant financial problems. His financial problems were usually caused by spending too much of his personal income on equipment, etc., needed in his research.

This introduction is based mainly on Steudel (2008), but bits here and there were gathered from Fulton and Wilson (1966) and Wight (2000). Because Müller was so eclectic in his research and information about him is so scattered, most of the entry will be written without citing specific references for each fact or set of facts, but all can be verified among the References at the end of this entry.

## Handbuch der Physiologie des Menschen

Among Müller's most memorable achievements was his *Handbook of the Physiology of Men* which was published in eight volumes from 1833 to 1840. Boring (1950) summarized each book's emphases as follows. Book 1 (288 pages) considered the circulation of blood and lymph. Book 2 (308 pages) considered chemical correlates of respiration, nutrition, growth, reproduction, secretion, digestion, excretion, and chylification (formation of chyle, which has complex functions in the intestines). Book 3 (270 pages) considered physiology of the nerves. Book 4 (248 pages) considered general muscular movement with special attention to voice and speech. Book 5 (256 pages) began with the formulation of the "doctrine" (Boring 1950, p. 35) or "law" (Finger 1994, p. 135) of specific nerve energies (more on this below) before considering the five senses. Book 6 (82 pages) was titled "Of the Mind" and considered association, memory, imagination, thought, feeling, passion, the mind-body relationship problem, phantasms, action, temperament, and sleep. Boring did not differentiate books 7 and 8 (179 pages for both) but noted that they considered reproduction and development, embryonic and postnatal. Boring considered books 3–6 most important for psychology.

### The Law of Specific Nerve Energies

Reduced to its essence, specific nerve energies (SNE) mean that each sensory nerve can only convey information to the brain that arises from the specific activation of the associated sensory receptors or nerves. There are corollary SNE associated with muscle activity, but the emphasis here is on the senses. To explain what SNE meant, Anonymous (1911) wrote:

... the kind of sensation following stimulation of a sensory nerve does not depend on the mode of stimulation but upon the nature of the sense-organ. Thus light, pressure, or mechanical stimulation acting on the retina and optic nerve invariably produces [only] luminous impressions (p. 962).

Boring gave less credit than most authors do to Müller for "discovering" SNE, but Boring did recognize Müller for its clearer formulation. Boring considered that the prior work by the

Scotsman, Charles Bell (1774–1842) and the Frenchman, François Magendie (1783–1855) in differentiating sensory and motor spinal nerves laid the groundwork for Müller's formulation of the concept of SNE (see Boring 1950, pp. 31–33).

## Other Accomplishments by Müller

Müller's research was so prolific that only a small sampling of his accomplishments can be mentioned here,

### Physiology

As noted earlier, Müller's dissertation dealt with locomotion in animals. He began with arthropods but eventually addressed locomotion in other classes of animals. In 1820, the Bonn Faculty of Medicine offered a prize to whoever could prove that a fetus can breathe in the womb. Müller confirmed that a prenatal lamb did breathe in its mother's womb. Using self-experiments and self-observation, Müller determined that optical perceptions can arise without an adequate stimulus, such as mystical visions including ghosts. It is unclear whether Müller realized that memories acquired via first- or second-hand reports might be the basis for such visions.

### Embryology

Many of Müller's contributions to embryology were methodological. He published on the development and structure of glands. He discovered the embryonic duct that formed the fallopian tubes, uterus, and vagina.

### Neurophysiology and Neurology

Controversy had arisen involving Charles Bell and François Magendie regarding priority for the discovery of the distinction between spinal sensory and motor nerves, and after Magendie retracted some of his findings as his methods had been questioned, Müller entered the fray. First, he tried to do research using rabbits that yielded ambiguous results. Müller then began to use frogs, which offered the advantage that the spinal cord is easier to remove with its functions well preserved, and the relationships between the nerves were more apparent. Müller's results using

frogs were unambiguous and reproducible; thus, was the validity of Bell's and Magendie's findings established. Müller went on to study cranial nerves. He showed that two branches of the trigeminal nerve were sensory and the third branch was predominantly motor but with sensory fibers that provided feedback from the muscles. Any student of neuroanatomy should be familiar with the intricate sensory-motor feedback loops that prevent muscles from over-contracting, thus detaching from the bones, yet sufficient to maintain muscle tonus. Müller also studied the glossopharyngeal, vagus, and hypoglossal nerves.

### Müller's Students and the Issue of Vitalism

Brazier (1959, p. 20) described Müller as the "greatest physiologist of his time" and a "gifted teacher." Müller had many more students than the few mentioned here: (a) Emil du Bois-Reymond was a pioneer in electrophysiology of muscle, (b) Theodore Schwann developed cell theory, (c) Rudolf Virchow was well recognized for his research on anatomical pathologies, (d) Ernst Brücke became a distinguished physiologist at the University of Vienna and was described by Sigmund Freud who studied with him for 5 years as his most highly respected teacher, (e) Carl Ludwig was the most distinguished physiologist at the University of Leipzig in his time where he significantly influenced Wilhelm Wundt. Ivan Pavlov studied with both Müller and Ludwig, and (f) Hermann von Helmholtz. Had the Nobel Prize existed in Helmholtz's time, likely he would have qualified for four: one for his research in vision, one for his research in audition, one for his formalization of the Law of Conservation of Energy, and one for being the first to measure the speed of nerve conduction.

#### "Vitalism: The Best and the Worst"

This heading is the title to chapter 4 in Meulder's (2010) biography of Helmholtz. It followed chapter 3, "Johannes Müller "Man of Iron." Most authorities agree that Müller was a vitalist throughout his career. Muelder raised some doubt about whether Müller was a vitalist at the end, but acknowledged

that his students, Helmholtz, du Bois-Reymond, Brücke, and Ludwig successfully branded Müller as a "vitalist."

Vitalism is the belief that living matter is sustained by a vital or "life force" that cannot be reduced to chemistry and physics. Biologists today believe that it was necessary to reject vitalism to enable biological science to progress. Between them, du Bois-Reymond and Ernst Brücke made a pact to compel and establish the truth that "No other forces than common physical chemical ones are active in the organism" (Boring 1950, p. 708). Helmholtz and Ludwig must not have been present for the pact, as they surely would have joined in.

Two of Helmholtz's greatest accomplishments served directly to refute vitalism. First was his determination that the speed of nerve conduction was approximately 150–180 ft/s (Cahan 2018, p. 93). Müller speculated that nerves conduct at the speed of light and that "We shall probably never attain the power of measuring the velocity of nervous action" (Boring 1950, p. 41). Such speculation and belief imply that nerve conduction was in the realm of the supernatural. Second was Helmholtz's formalization of the Law of Conservation of Energy. Cahan (2018, p. 151) summarized the Law as follows:

Nature as a whole contained a store of force . . . that could be neither Increased nor decreased; its total quantity was "eternal and unchangeable like the quantity of matter."

There is an emerging parallel to vitalism that is plaguing animal cognition research today, namely, an advocacy for emergent properties. Here such advocacy will be termed "emergentism." Duane Rumbaugh and his colleagues have been at the forefront of such advocacy. Anonymous (2009) wrote:

Throughout his professional life, Rumbaugh has sought ways to test and understand intelligence that does not depend on the human capacity for complex language. In addition, he has sought to go beyond the two traditional methodologies: "respondents," innate, involuntary reactions to stimuli based on conditioning; and "operants," limited, voluntary actions that are designed to gain an award through operating on a particular environment. Rumbaugh has added a new methodology: "emergents," which are unusual problem-solving behaviors that are not based on repetition or

associative learning, but instead seem to emerge from a kind of integrative process based on genetics, instinct, and cognitive reasoning.

See also Rumbaugh (2002) Rumbaugh et al. (2003) and Rumbaugh et al. (1996). Belief in emergentism accepts that behavioral scientists may investigate phenomena that are not in principle reducible to physics and chemistry.

Emergentism has its roots in the nineteenth century theory of “mental chemistry” advocated by the philosopher, John Stuart Mill. Interestingly, John Stuart Mill’s view was in opposition to his father’s advocacy of “mental mechanics.” In brief, John Mill believed that “the whole is equal to the sum of its parts” versus John Stuart Mill’s belief that “the whole is greater than the sum of its parts.” As “proof” of mental chemistry, J. S. Mill used water to argue that water has properties that cannot be predicted from its elemental constituents’ oxygen and hydrogen. The “mental mechanist” would counter that when we know all the properties of hydrogen and oxygen, we will be able to account for all the properties of water.

In other words, to be a vitalist or emergentist promotes giving up and avoiding the hard work necessary to establish the physicochemical foundations of biological and psychological phenomena. For a more detailed account of the hazards of and parallels between vitalism and emergentism, please see Thomas’s entry, “Morgan’s canon” in this *Encyclopedia*.

## John B. Watson

John C. Malone

University of Tennessee, Knoxville, TN, USA

More than other intellectual pioneers, John B. Watson’s views have been so simplified and distorted by successive generations of authors that it is difficult to discern his actual message. Watson founded behaviorism in 1913; the difficulty lies in

the fact that this doctrine directly contradicts the ancient folk psychology that forms the basis for our languages and for our strongly ingrained beliefs. Most readers, including almost all psychologists, have escaped the difficulties by adopting a simplified and false interpretation of his doctrines and leaving it at that. In fact, most handbooks and textbooks corroborate that falsely caricatured version.

Todd (1994) surveyed textbook treatments of Watson over the decades and found that they became “standardized” after 1960. According to that portrayal, Watson “appeared suddenly in 1913” and promoted a narrow brand of psychology that assumed that all behavior was learned and that led to an unethical “baby-frightening experiment.” Given the mass of work Watson produced studying instinct in animals in the laboratory and the field and the countless infants he worked with in Baltimore, he would have been exasperated, but probably not surprised, to read such a summary.

The purpose of this essay is to correct the record by concentrating on a few major aspects of his work. Many complete accounts appear elsewhere (Buckley 1989; Malone 1990/2004, 2009; Malone and Garcia 2014).

## Introduction

John Broadus Watson was born in 1878 on a farm near Greenville, South Carolina. He earned a master’s degree in 1899 at Furman University in Greenville and went on to the prestigious University of Chicago, where he became the youngest recipient of a PhD and remained as an instructor. He soon established a reputation as a researcher of animal behavior, and in 1908 the opportunity of a lifetime arose when he was offered a professorship and department chairmanship at the Johns Hopkins University in Baltimore. Watson also became editor of the *Psychological Review*, affording him tremendous influence over the development of psychology. Malone (2014) noted that he was “. . . attractive, strong, scientifically accomplished, and forceful” at a time when other psychologists and zoologists “. . . seemed weak, tentative, mealy mouthed, and ineffectual.”

Watson was combative and articulate, a real fighter who dismissed the psychology that existed at the time. And he was a full professor at Johns Hopkins at the age of 29! He was universally respected as both a researcher and scholar and came with a plan for action, rather than traditional quiet discussion and polite debate.

Watson had begun his career in the study of animal behavior (Malone 2017), both in the laboratory and in the field, including physically demanding research on noddy and sooty terns in the Dry Tortugas. He clearly considered himself a comparative psychologist and 80 years later so did comparative psychologist Donald Dewsbury (1994). But after 1915 his interest centered on child development. His academic career was cut short in 1920, partly due to a scandalous divorce (Buckley 1989; Malone 1990/2004). Isolated from academics, he began a very successful second career in advertising, first with J. Walter Thompson agency and later with William Esty. He continued to lecture occasionally and published frequently, but usually in popular magazines. His influence on modern psychology was evidenced in 2014, when the centennial of his 1913 seminal lectures announcing the founding of behaviorism was celebrated by the Association for Behavior Analysis International (ABAI) and the publication of many testimonial articles. It is commonly known that he established behaviorism, a movement that fractured (or blossomed) into many disparate parts over the years.

## Behaviorism

This is a way of treating the entire subject matter of psychology as activity, or behavior. That seems a simple thing to say, but its implications are difficult for many people to grasp and easy to misunderstand. Imagine that common psychological terms like “memory” and “visual images” are replaced by “remembering” and “seeing.” Instead of things like memories and images that are somehow stored in the brain and perceived by an inner ghost, we treat the psyche only as activities and dismiss our childish notions of bodies with computer brains controlled by magic spirits. When Watson proposed that we can study psychology

in an objective way, just as we study the rest of the physical world by concentrating on behavior, some listeners and readers were enthralled, but most were shocked. They believed in 1913, as they believe now, that Watson had forbidden the study of the mind!

Watson was not limiting psychology; Hilgard (1987) argued that he was expanding its field of study. Psychology had been obsessed with the analysis of consciousness, restricted to humans able to understand and use language and who were more or less sane. They were trained to “introspect” and describe their conscious experience using labels that they were taught, like “sensation,” “feeling,” and “image.” Behaviorism, on the other hand, applied to children and other non-verbal individuals, as well as subhuman animals and the insane.

## Consciousness?

Watson argued that the concept of consciousness derives from the invention of the soul by lazy but clever ancients who discovered that they could manipulate people through fear of the supernatural (1924). In both the 1924 and 1930 editions of *Behaviorism*, it was “The Advent of the Behaviorists” that first began to set things straight by banishing the soul, consciousness, and other fictional subjective terms and so providing a psychology that is “as objective as baseball.”

The assumption that we have minds that operate our body machines is pure folk psychology. Watson never argued that minds exist but are not objective, so cannot be studied. This misunderstanding has persisted for a century. He actually said that there is no “mind!” There are activities like seeing, hearing, listening, remembering, and imagining, but do they constitute a “mind” that is separate from the body?

Watson emphasized repeatedly that the mind/body distinction is a false one, writing that “Surely no one could ever be bold enough or rash enough to question that there is such a thing as mind or that it is made up of conscious units. And yet this is just what the Behaviorist did” (1926). We do not study the Easter Bunny

(or the mind) because there is no profit in studying things that exist only as words. The mind/body distinction was invented by savages and, though incoherent, was passed on as folk wisdom that is believable only because it is drilled into us in our language. The cultural belief in mind and body does not make minds exist.

Similarly, does the word sensation mean anything? If not, why try to analyze our experience into sensations? Or, as Watson urged, should we study the conditions that produce reports of “red” and the range of stimuli to which we are sensitive and the conditions that cause red/green confusions, as he did with a variety of animal subjects (Malone 2017)? Do we really want to hear your description of the feeling of “redness” or my description of the feeling of the chime of a bell? But that was psychology in 1913.

## Reactions to Watson’s Behaviorism

No one enjoys watching their life’s work dismissed, especially when the movement responsible gains traction and acclaim as revolutionary. Woodworth (1931) referred to “the outbreak of behaviorism” as if the movement was a disease. Behaviorism was a “youth movement,” and Woodworth disapproved of the fact that Watson “had won the public ear” (1931). He was unhappy with reviews of *Behaviorism*, Watson’s (1924 1930) flagship book: “The *New York Times* said of the book, ‘It marks an epoch in the intellectual history of man.’ The *Tribune* was more effusive: ‘Perhaps this is the most important book ever written. One stands for an instant blinded with a great hope’ (Woodworth 1931). And Woodworth was neither the only critic nor the harshest. Jastrow (1929) was furious, referring to Watson’s “extravagant and irresponsible claims... superman-ic disdain for one’s fellow scientists,” coming from someone whose “standing is unchallenged, his ability exceptional, his contribution notable.” That made Watson’s hostility toward conventional psychology even more egregious, as if a “modern Machiavelli” was seeking to confound the world. Watson was using the prestige and authority he had earned to “throw

the labors of everyone else into the discard. . .” (Jastrow 1929).

More recently, Harzem (1993) provided a detailed account of the harsh treatment Watson received from the psychological establishment, the press, and powerful enemies after his sensational divorce in 1920 and his departure from a pinnacle of academic success at Johns Hopkins. Harzem wrote that Watson had “dismissed at one stroke the entire body of literature on experimental psychology. . . painstakingly built over many decades. . . the academic reaction to this action was strong.”

Even today, it is difficult to find a textbook or handbook or encyclopedia entry that presents a fair rendition of Watson’s views. The leading biography of Watson is generally well done, but Kerry Buckley (1989) mistitled it *Mechanical Man*, implying a robotic/erector set orientation. Watson’s behaviorism holds that explanations must deal with our activity (behavior), not with supposed underlying, usually hypothetical machinery. But like the cat attracted to the laser pointer spot, the public is fascinated by colorful brain scans, believing that they somehow explain the workings of the mind. Watson was expert in biology, yet included no illustrations of brain mechanisms, since he knew that a nervous system was not necessary for intelligent behavior and that attributing behavior to the brain was only a distraction. No reader of his books could conclude that Watson denied private experience and treated us as complicated machinery; ironically, that better describes many cognitive theories! Yet, long after his death in 1958, his famous descendent B. F. Skinner showed no hesitation in throwing Watson under the bus while damning him with faint praise (e.g., 1974) and implying that Watson was guilty of the list of such sins (like portraying us as automatons) that are often still attributed to all behaviorists.

## Mary Calkins Understood

Mary Calkins (1930) had studied under the great William James in the 1890s, and she correctly understood Watson’s behaviorism. In 1930 she

distinguished between “moderate” and “extreme” behaviorism, which roughly corresponds to what Skinner (1945) would call “methodological” and “radical” behaviorism. The former holds that the mind cannot be treated by science because it is subjective, a position never held by Watson or by Skinner, but which is often attributed to both. The latter, radical behaviorism, promoted by Watson and named by Skinner, holds that mental terms are fictional products of folk psychology and that the mind/body distinction is a false one. Calkins was more perceptive than most psychologists who followed, since she recognized that Watson’s behaviorism was the radical kind and she wrote, “Rather, no theory is rightly called behaviorism which does not effectively ‘scrap’ mind and consciousness alike,” published the year she died (1930).

Though Watson claimed in 1936 that he never understood John Dewey’s lectures when a student at Chicago, the professor and the graduate student shared some important beliefs. According to Dewey (1930), modern justification for mind/body dualism comes in part from physics, of all sources, and he probably was thinking of Galileo when he wrote, “Qualities ejected from physics found a home in mind, or consciousness.” This is because Galileo viewed reality solely as physics and dismissed sensations, like “warm” or “bright,” as unreal, since they are subjective. Dewey pointed to “. . . the authority of physics for taking them to be mental and psychic in nature.” The separation of physics and sensation “. . . created. . . the beginnings of modern psychology and impregnated its terminology. Behaviorism is a reaction against the confusion created by this mixture” (Dewey 1930).

So “mind,” “consciousness,” “sensation,” “image,” and other terms are jargon, fictions that have no referent, but they “impregnated” our terminology. If Watson asked you to define those mental terms, he claimed that you would soon be “tongue-tied” since “you don’t know what you mean by them” (1924). Bergmann (1956) famously displayed a complete misunderstanding of Watson’s behaviorism writing, “His premise, that there are no minds, is false and sheer nonsense. . . when. . . I speak of minds, these are

so-called mental contents, or awarenesses, or phenomenal givennesses. . .” (Bergmann 1956).

Bergmann confused Watson’s denial of mental causes, like mind, sensation, and the rest, with denial of seeing, imagining, thinking, and other aspects of private experience that were never denied by Watson or by anyone, *ever*. This is always a contentious subject, because most of us feel that we experience imagery and it’s easy to recoil when someone tells us that there are no “images,” as Watson did and as Skinner later agreed. But even cognitivists agree that there are no “pictures in the head, so there is no argument among most psychologists today (see Malone 2009). There are better descriptors than “phenomenal givennesses,” such as “qualia,” but whatever they’re called, pieces of private experience are not “mental content,” and they’re not causes of observable behavior or speech; they are also behaviors/activities that are part of the fabric of all behavior. How experience “feels” is best left to the humanities to describe.

Nonetheless, the astute Mary Calkins (1930) also had her doubts that behaviorism could replace the study of consciousness wondering, “Is thinking merely a kind of doing?” We wonder (with Watson) what else it could be. Consider first Watson’s bare-bones “theory of learning;” once understood, his views on thinking, emotion, child development, and psychopathology become clear.

## Pattern Reactions

In 1919 Watson wrote that we are “what we come with and what we have been through,” and the latter is by far the most important. We come with a set of innate reactions called out by specific stimuli, so touch produces movement, an air puff causes a blink, food in the gut produces peristaltic movements, an object crossing the visual field causes orienting and following, and a sudden noise causes fear reactions. In the womb the infant reacts incessantly, adjusting to constantly changing stimulation, and adjustment continues until death, the final adjustment.

Through life, we adjust, constantly, with the whole body. These *pattern reactions* comprise three general categories: manual (M), “laryngeal (L),” and visceral (V), corresponding to motor, communicative, and emotional behaviors. Whether calm or agitated, reading or walking, asleep or awake, these three classes of behavior simultaneously are active, though in different degrees. For example, quiet reading may show low levels of manual and visceral behaviors and higher levels of laryngeal activity, as could be symbolized mLv. That could change in a moment if we react to the sound of a scream, becoming MLV.

This principle applies easily to learning, say a baby learning to grasp a bottle, which it does “by the sweat of its brow” (Watson 1919). The shiny object calls out its whole set of reactions – arms, legs, vocal cords, salivation, and stomach secretion – the MLV set. Eventually, the bottle is pushed away or grasped and adjustment is achieved. The evoking stimulus has changed and whatever behavior accomplished that will be likelier to occur when such a stimulus recurs. That behavior will also occur when similar stimuli appear, and this acquisition of old responses to new stimuli forms the basis for all learning and the formation of one’s personality.

## Embodiment

Watson repeated often that we adjust with the whole body – “Let me emphasize again – *whole*” (1924). And we place “. . . no more emphasis on the brain and spinal cord than upon the striped muscles of the body, the plain muscles of the stomach, the glands, etc. . .” (1924). In fact, a nervous system merely “speeds up the message,” but the message still gets through in the absence of a nervous system, just more slowly (1924). As a biologist, he also realized that the whole body is *alive*, therefore not really “mechanical,” in the sense that we usually refer to nonorganic devices such as erector set robots.

Watson's *Behaviorism* presents psychology as the activity of the whole body. In current cognitive jargon, that is "the embodiment of mind," described well by Killeen and Glenberg (2010), who trace the history of the "situating" of mind from Descartes to the present. Watson would be pleased to see that the old "information processing" model is now becoming passé, as we realize that digital computers are awful models for organic intelligence. Louise Barrett (e.g., 2011) showed how powers that were previously ascribed to the brain are actually explained by body structure and the environment, just as Watson and many modern writers argue. As Watson pointed out, there are "...many animals and free swimming plants without nervous systems" (1924, p. 43). This is not to say that a central nervous system is superfluous, but many writers have joined Barrett (2011) in condemning the brain reverence of the past century (e.g., Tennenhouse 2017).

## Thinking

Watson wrote that "...man both talks and thinks with his whole body – just as he does everything else with his whole body" (1930). But earlier he had *suggested* that laryngeal movement was an important physical embodiment of thinking, as well as talking (e.g., 1913), and this was seized by critics eager to show that a functioning larynx was not essential for thought. But even his contemporary critics recognized that interpreting thinking as "behavior" did not necessarily mean activity of the laryngeal vocal apparatus.

Watson dealt with this specific issue in both editions of *Behaviorism* (e.g., 1924) and earlier when he issued "A Correction of Statement" in 1920 at the Congress of Philosophy that met at Oxford. He wrote, "In advance of any argument I think we can say that he (the behaviorist) has never really held the view that thinking is merely the action of the language mechanisms... Like everything that we do thinking is done with the whole body." Further, if the body is damaged so

that limbs or organs are missing, "he thinks with the remaining parts... thinking, whatever its type, is an integrated bodily process."

## Silent Problem Solving

When problem solving, our behavior is no different from that of a rat learning a maze. Suppose a man is given a gold cigarette case with a secret release mechanism and told that he can have the case if he can figure out how to open it (Watson 1920). We watch as he spends several minutes manipulating it but fails to find the release mechanism. Now we send him away to a room by himself and tell him to come out when he has figured it out. After a few minutes, he comes out and proudly shows that he has figured out the trick to open it. But how did he do it? We didn't see what he did when he was sent to that room. But we saw him at work for several minutes before entering the room – why would we suppose that he did anything different once we couldn't observe him? The parallel with observable behavior and thinking is obvious; just because we can't see or hear the process doesn't mean that it is different in kind from the problem-solving behavior that we do see.

## Other Thinkers

To *really* understand another's "thinking," the behaviorist, "as well as the psychoanalyst... (require) a minute search into the subject's biography as far back as infancy" (1920). Watson went on to criticize the study of moment-by-moment private experience since that requires introspective training, with the subject repeating the labels for "conscious experience" that were just taught – what else could they be? He continued, "The report by the subject throws very little light." The same applies when the behaviorist considers his own thinking, which yields little via introspection and really requires examination of one's own life history. However, we find that most of our past experiences were not verbalized, and the body of

that wordless “memory” constitutes the unconscious. Watson suggested that “The theory of the unverbalized in human behavior gives us a natural science way of explaining many things that the Freudians now call “unconscious complexes,” “suppressed wishes” and the like” (1930). This explains Watson’s respect in his early work for the methods of psychoanalysis.

## Psychoanalysis

Watson criticized psychoanalysis in his last works, just as he criticized all “subjective psychology.” But for decades he approvingly cited Freud and even published a detailed endorsement of Freudian psychoanalysis in 1916, when Freud had not yet become a household word. This was a scholarly piece, published in *The Scientific Monthly*, which Watson concluded by arguing that everyone who dares should undergo psychoanalysis. This applies especially to those occupying stressful high-level government or business positions, so that their pressures are not augmented by the stresses of unresolved conflicts arising in childhood and youth that they are incapable of verbalizing! Years before and after that article, Watson referred repeatedly to Freudian psychology, criticizing some of its language, but endorsing it in general. Perhaps surprising, Watson was a conspicuously vocal defender of Freudian psychology, though Freud never realized this (Bergmann 1956).

## Psychopathology

The adjustments we make through life produce sets of reactions to the innumerable situations we have encountered, and those reactions are organized so that we can also adjust to new situations. Though “new” unfamiliar circumstances resemble familiar situations to some degree and the more they resemble the familiar, the easier the adjustment. So a person familiar with high school can adjust to college easily, but the adjustment to military life may be more difficult, since it includes stimuli that demand responses we lack.

Our learned adjustments total to become our personality, and a well-adjusted personality can deal with new situations that are encountered. But what if the new situation is so novel that it leaves us unable to adjust?

As Watson wrote, “Almost any event or happening might start a change; a flood might do it, a death in the family, an earthquake, a conversion to the church, a breakdown in health, a fist fight – anything that would break up your present habit patterns. . .” (1930). Recovery from such trauma may be difficult and lengthy, since it requires a rebuilding of personality. We do not learn chemistry or become a piano virtuoso in a day, and reshaping a personality may be more difficult than either, but Watson was sure that it could be done.

## Advertising and More

In 1920 Watson was 42 years old and left Baltimore for New York City, banished from academics and embittered; the publicity produced by his divorce and the viciousness of his former wife’s influential family was too much (Buckley 1989). He was introduced to people associated with J. Walter Thompson Advertising Agency and provisionally hired. By 1924 he was a vice president and became a wealthy man, living first on Fifth Avenue and later on a 40-acre “farm” in Westport, Connecticut.

Watson could have dedicated *Behaviorism* to Pavlov, or Darwin, or Bertrand Russell, but both editions were dedicated to Stanley Resor, who led the J. Walter Thompson Advertising Agency from 1916 to 1955. With his wife’s creative genius behind ad campaigns, Resor built JWT into a worldwide power, eventually setting records in billings. The dedication to Resor owed to that man’s “unfailing interest in both industry and science,” an interest shared by Watson, clearly evidenced in his 1913 manifesto. According to the archives of JWT, “To foster a scientific approach to advertising the company established a Research Department in 1915 and hired eminent academics such as John B. Watson, the founder of behavioral psychology. These professionals

added a new dimension to marketing research as J. Walter Thompson applied motivational studies to advertising, initiated the use of scientific and medical findings as a basis for copy, and established the Consumer Panel. . .” (J. Walter Thompson Archives).

The behavioral approach to advertising was simple and effective. His research with infants suggested that there are three innate emotional (visceral) reactions – fear, rage, and love. The cues related to each of those, plus food, sex, and shelter, can form 720 combinations and should be used in advertising displays as often as possible to attract the viewer’s attention. So Johnson’s baby powder came to signify love, by pairing its image with that of a loving mother patting a healthy, happy baby. Scott’s toilet tissue was paired with imagery of a bowel surgery and the warning that harsh toilet paper can lead to scary results. Further examples appear elsewhere (Malone 1990/2004). Walter Dill Scott had already changed advertising from informative to persuasive. But Watson carried that strategy further than it had been applied, and he is credited for it in advertising circles (*Advertising Age* 1999).

It appears that Watson’s legacy to business was more than just his work with advertising copy. He also produced innovations in personnel selection and management, as noted by DiClemente and Hantula (2000), who scoured the Library of Congress for documents providing a more complete picture of Watson’s business life and legacy. They wrote, “Indeed, the terms ‘behavioral’ and ‘experimental’ are often used to describe Watson and his work, and they have overshadowed his contributions to I-O psychology. . .many of his ideas endure today. . .He pioneered much of the work in selecting successful sales people and argued for personality testing in personnel selection before ‘The Big Five’ were introduced to contemporary research. . .This may be perhaps his lasting legacy. . .”

## Remembered by His Son

Watson’s son James was interviewed by Hannush (1987), providing an account of memories of life

with his father, with “no promises about objective observation.”

James remembered his father as having a sense of humor, as charming, and “a delightful person to be around.” He was bright, sociable (yet shy), fastidious, and *masculine*. James said that “Dad was very concerned with manly activities. . .courage and personal capabilities. . ., bravery and manliness, manual work, farm work, carpentry, and all of the manly arts including boxing.”

He showed more affection for animals than for people, and the only times he expressed much anger was when he saw “cruelty or abuse of other people or animals. . .cruelty to animals and children. . .That’s something he couldn’t stand.” He always had a huge garden and he was a skilled carpenter, who built bridges, barns, greenhouses, workshops, corrals, riding rings, dams, and stone walls.”

Watson’s so-called “behavioral” method of child raising was totally idiosyncratic and forbade any displays of warmth or emotion; James attributed his difficulties in life and his brother’s suicide to that upbringing, which he thought left them without the self-esteem necessary for a healthy life. He wrote, “Tragically, that’s the antithesis of what Dad expected from practicing those behavioral child raising philosophies.”

Following Rosalie’s death in 1936, Watson was devastated and seemed “confused” and depressed for several years. James was barely a teenager when she died, and his recollections of his father, then in his late fifties, show a less combative man. James could only say that he had “heard about” his father’s competitiveness and aggressiveness in his earlier career, but it evidently diminished after Rosalie’s death.

## John Bowlby

Miranda Goodman-Wilson  
Eckerd College, St. Petersburg, FL, USA

## Introduction

John Bowlby is best known as the father of attachment theory. First developed in the 1950s, attachment theory was both shaped by and significantly influential on the study of animal behavior. This entry will describe Bowlby's biography as it relates to the development of attachment theory, the major principles of and significant influences on his theory, and its applications to animal research.

## Early Life

Edward (John) Mostyn Bowlby (1907–1990) was born in London, England, to an upper-middle class family. As was characteristic of the time, he and his five siblings were raised primarily by a series of nannies and nursemaids. Bowlby only visited with his mother for an hour each day and with his father considerably less. His first nursemaid, Minnie, served as a mother substitute for him, and when she left the family when Bowlby was four-years-old, it served as a devastating loss. This would prove to be profoundly influential on his later research interests (Van Dijken 1998).

## Education and Clinical Experience

At the age of 11, Bowlby was sent to boarding school and at 14 entered the Royal Naval College, Dartmouth. In 1924, after spending less than a year training on a naval ship, Bowlby decided to leave the navy and pursue the study of medicine (Van Dijken 1998). He received his undergraduate degree from Trinity College at the University of Cambridge in 1928. While there, Bowlby recalled focusing a considerable amount of his time on evolutionary biology, which would prove influential on his development of attachment theory (Van Dijken 1998). He was also introduced to the field now known as developmental psychology, then in its nascence (Bretherton 1992). This persuaded him to leave his studies in medicine for psychology for the remainder of his undergraduate years. He would, however, return to the field to medicine, earning his degree from London's University College Hospital, in order to pursue a career in psychiatry. This was partially influenced by his work at a school for maladjusted children where he encountered children whose psychological problems appeared to be closely linked to their early childhood experiences of parental deprivation. Witnessing this association between early familial relationships and later development solidified Bowlby's interests in child psychiatry (Bretherton 1992).

As Bowlby pursued his studies in medicine and psychiatry, he also began training in psychoanalysis at the British Psychoanalytic Institute. His supervisor, Melanie Klein, shared his interests in early relationships and the damaging effects of early loss. However, as was characteristic of the field at the time, Klein's focus was almost exclusively on unconscious processes, to the exclusion of examining the actual experiences of children. Bowlby rejected this premise and sought out to prove that real-world experiences of trauma and loss have the most powerful influence on personality development (Bretherton 1992). This was supported by his first empirical paper which traced the development of 44 juvenile thieves back to their history of early separation from their mothers and other adverse childhood experiences (Van Dijken 1998).

Following the completion of his psychiatric and psychoanalytic training, Bowlby was appointed head of the Children's Department at Tavistock Clinic, an organization focused on social and preventative psychiatry. It was here that attachment theory was first developed.

## Development of Attachment Theory

### Core Tenants of Attachment Theory

At its core, attachment theory argues that the parent-child relationship is critical for both the child's immediate survival and their long-term psychological well-being. In Bowlby's writings, this is traditionally described as the mother-child relationship although he acknowledged the role of "mother substitute" figures, perhaps harkening back to his own childhood experiences with his nursemaid. Bowlby's theory is based in both developmental psychology and ethology. He argued that the attachment relationship is built upon a series of instinctual behaviors designed to bond infants and mothers together in order to ensure that the vulnerable infant receives the care they need. This need for protection, and the depth of the bond formed, helps to explain why infants demonstrate such significant separation

anxiety when apart from their mothers and why long-term separation can have such devastating psychological consequences, as Bowlby observed in his studies of maladjusted children and juvenile thieves (Bowlby 1982; Bretherton 1992).

Bowlby defined attachment as a behavioral system, similar to but separate from mating or feeding, which has evolved to promote the survival and reproductive success of the individual. In the case of the attachment system, the infant is drawn to maintain proximity to their attachment figure (the person who is most responsive to the infant's needs for care). As the child develops, so does the attachment relationship, becoming what Bowlby described as "goal-corrected partnership" as the child becomes more attuned to their caregiver's psychological perspective. Bowlby also argued that children's experiences with their attachment figures become mentally represented via what are known as "internal working models" (IWMs) which are then used as a way to predict future interactions with relationship partners and the world in general (Bowlby 1982).

### **Collaboration with Mary Ainsworth and the Assessment of Attachment**

Several years after Bowlby's arrival at the Tavistock Clinic, a scientist by the name of Mary Ainsworth joined his research unit. It was Ainsworth who completed the first empirical study of attachment, observing 26 families with infants living in Uganda over a period of 9 months. It was here that Ainsworth first noted three distinct patterns of attachment-related behavior: babies who seemed content in the presence of their mothers and explored comfortably under her supervision (now classified as securely attached), those who cried frequently in her presence and explored little (insecure ambivalent), and those who showed little regard for whether or not their mother was present (insecure avoidant). Upon returning from Uganda, Ainsworth began a second observational study of 26 families in Baltimore where again Ainsworth was struck by the individual differences in how both infants and mothers responded to each other (Bretherton 1992). From this work, Ainsworth developed a

standardized laboratory procedure, the Strange Situation, which was designed to capture the quality of the infant-parent attachment relationship over the course of a 20-min observation (Ainsworth et al. 1978). The Strange Situation is still considered the gold standard for attachment assessments, and Ainsworth's empirical work helped to provide evidence in support of Bowlby's theory.

### **Ethological and Comparative Psychology Influences on Bowlby's Work**

Bowlby's theory of attachment was born out of his education and training in both developmental psychology (which, at the time, was heavily steeped in psychoanalytic theory) and evolutionary psychology. In taking an evolutionary approach to explain the origins of the attachment relationship among human parents and children, Bowlby recognized that this type of relationship was also likely to exist in our closest evolutionary kin. He was also interested in attachment-related behaviors, such as imprinting, which are present in other species. For example, Bowlby was drawn to Konrad Lorenz's research on imprinting in goslings, which demonstrated the critical role that the parent-child connection plays in promoting the survival of vulnerable young. Bowlby was also drawn to Lorenz and others' ethological approach, which requires the observation of animals in their natural environment, and was similar to Ainsworth's work in Uganda and Baltimore and other research being conducted at Tavistock (Bretherton 1992).

Although Bowlby favored an ethological approach to animal research, he was also deeply influenced by the work of Harry Harlow who used experimental methods to study affectional bonds in rhesus monkeys. Harlow was particularly interested in the effect of parental deprivation on infant monkeys. In 1957 Bowlby and Harlow began a written correspondence which eventually led Bowlby to visit Harlow's monkey laboratory at the University of Wisconsin. Bowlby often cited his observations at Harlow's lab in explaining the behavior of human infants, for example, linking pathological thumb sucking in children to the nonnutritive sucking behavior demonstrated by

monkeys who had been raised in isolation (van der Horst et al. 2008).

## Contributions to the Study of Animal Behavior

As Bowlby recognized, the attachment bond is not unique to the human species. This fact has long been supported by research with nonhuman primates, including chimpanzees and rhesus monkeys. It is worth noting, however, that attachment relationships are not universal across primates. Research on New World monkeys, such as capuchins, and prosimian species has demonstrated that they imprint on their mothers but do not form the complexity of an attachment bond (Suomi 2016).

The study of rhesus monkey attachment dates all the way back to the 1950s with Harry Harlow. Just as Harlow's work was influential on Bowlby as he developed attachment theory, so was Bowlby's new theory influential on Harlow's subsequent research. For example, in a series of experiments, Harlow tested Bowlby's theory of separation syndrome (the stages of protest, then despair, that Bowlby argued human children demonstrate when separated from their caregivers) by separating infant rhesus monkeys from their mothers (van der Horst et al. 2008).

An extension of Bowlby's theory has been the physiological mechanisms of attachment. This research has its origins in the study of stress responses in rat pups and thus represents a feedback loop between the study of human and animal behavior. Bowlby had already proposed that, in humans, separation from an attachment figure represents a signal of danger. The precise physiological responses of rats separated from their mothers have been meticulously tracked through a series of experiments that would be impossible in human children (Polan and Hofer 2016).

The tools to assess individual differences in attachment have also been extended to the study of nonhuman species. For example, Mary Ainsworth's Strange Situation Procedure has been adapted to assess the owner-dog relationship (Rhen et al. 2013; Topál et al. 1998). Results from

these studies generally support the idea that dogs do form attachment bonds with their owners, which can be assessed along the same dimensions of security and insecurity as the parent-child attachment relationship. The same research has been extended to the study of the cat-owner relationship although there is little evidence of an attachment bond with owners within the feline species (Potter and Mills 2015).

## Conclusion

John Bowlby was a pioneer in the field of human psychology, but his work has long-reaching influences on the study of animal behavior as well. This is fitting given how steeped in ethology and animal research the development and application of attachment theory has been. Nearly 60 years after it was first developed, Bowlby's attachment theory continues to generate new research in both human and nonhuman species. Indeed, the lasting generativity of attachment theory is relatively unique in the field and sets John Bowlby apart as one of the most influential psychologists of the twentieth century.

## John David Smith

Michael J. Beran

Department of Psychology, Language Research Center, Georgia State University, Atlanta, GA, USA

J. David Smith received his B.A. in Anthropology from Yale in 1975. His background and course training in music, music theory, composition, and counterpoint led to an honor's thesis on the cultural shaping forces that produced the music and the music-theoretic structure of Indonesia's Gamelan. At this point, David aimed toward graduate study in ethnomusicology. In his early career, David made significant contributions to the study of music, cognition, and aesthetics (e.g., Smith 1987; Smith and Melara 1990). He has

also taught courses in these topics for many years at the graduate and undergraduate level.

Seeking a contribution through public service, David entered the Teacher Corps from Yale. He worked for two years as a classroom teacher at schools in Spanish Harlem. Concurrently, he completed coursework and requirements at the Bank Street College of Education, receiving in 1977 an M.S. Ed. in Early Childhood Education. These experiences, and his thesis on cultural differences in cognitive styles and their impact on educational success, led David toward graduate study in cognitive psychology and cognitive development. He has taught many courses in development, education, testing, intelligence, and socioeconomic influences in these areas.

David received his Masters and Ph.D. in Psychology (Cognitive) from the University of Pennsylvania in 1982, advised by Deborah G. Kemler Nelson and Jonathan Baron, with important influences in cognitive-developmental psychology by Rochel Gelman. Equally important, David was taught at Penn by an extraordinary group of behavioral and comparative psychologists, including Richard "Dick" Solomon, Robert Rescorla, Randy Gallistel, Paul Rozin, and David Premack. At that time, Penn may have had no equal for training in behavioral and comparative psychology. David still remembers with awe his riveting first seminar with Solomon. He was well prepared to extend his scholarship into the field of comparative cognition when the time came.

In fact, David has always approached his studies in animal cognition from a perspective shaped by human cognitive psychology. For example, David realized, after teaching, and teacher training, and two masters theses on cognitive-developmental issues, that scholars were misunderstanding humans' high-level cognitive capacities in important ways. Considering metacognition, in particular, they interpreted that capacity as highly verbal, declarative, and explanatory. So they also tested the capacity in children in that way. They made this interpretation to the point that even children at age 6 or 7 often seemed not to be metacognitive, because they would fail some of the existing assessments. David was

struck by the conflation with language and with introspection that needed to be explicitly declared. Surely metacognition in its essence might be language quiet while still introspectively lively, undeclared but still available for behavioral use by the organism.

Many comparative psychologists will know where this train of thought led. It produced an influential new area of research exploring animals' metacognitive capacities (e.g., Smith 2009; Smith et al. 2003, 2012b). David's initial studies with rats were not published because those rats, in the method adopted, did not express any metacognition. The verdict is probably still out on rats, considering the multiple studies completed since. But then a dolphin clearly showed a data pattern that might be construed as metacognitive (Smith et al. 1995), prompting a long and sharp debate in comparative psychology about theoretical interpretation and about the appropriate methods for tapping metacognition (Carruthers 2008; Crystal 2014; Hampton 2009; Kornell 2014; Smith et al. 2008a, 2009). The dam burst, with many ensuing studies on various species of vertebrates (e.g., Beran et al. 2012). David explored the case of the New World and Old World monkeys principally (e.g., Beran 2014; Smith et al. 1998, 2006, 2010b, 2013; Zakrzewski et al. 2014), creating new paradigms and building the case that some nonhuman primates have a form of metacognitive monitoring that is on the spectrum toward humans' full-fledged metacognitive capacity. After a long debate, this interpretation is now the majority interpretation in the field.

Given his educational background and developmental training, David also has a lifelong interest in concepts and category learning, together with their underlying neuroscience. His work in this area helped produce a sharp rebalancing of theory in the human categorization literature. In this rebalancing, the dominant exemplar theory was sharply delimited to its proper, small domain of application, while prototype theory's importance was appropriately expanded (e.g., Smith and Minda 1998, 2000, 2002). This research was important in resolving a 30-year-long difficult debate in cognitive psychology.

Remarkably, David's animal studies were instrumental to this resolution. His experiments on pigeons, capuchins, and macaques, as much as his results from humans, showed clearly that many vertebrate species do not memorize all of the specific exemplars they encounter, which is the central tenet of exemplar theory (Smith et al. 2008b). Rather, they inherently abstract and average their exemplar experience, forming central-tendency category representations or prototypes (Smith et al. 2010a, 2012a, c). In this area, there was an extraordinary synergy between David's cognitive and comparative research, as the animals helped establish the roots of humans' categorization, and helped reveal the essential truth about vertebrates' categorization processes that probably run tens of millions of years deep.

In collaboration with the Federal Aviation Administration and the Transportation Security Administration, David applied his expertise on concepts and categories to the problem of Homeland Security. He studied the difficult threat-recognition problem that airport X-ray screeners face and explored ways to improve the level of threat detection within the security system. This research showed that the visual search for threat targets elicits highly-specific recognition processes that generalize poorly to novel tokens of target/threat categories (e.g., Smith et al. 2005). Thus, though screeners may become excellent at detecting in baggage the specific knives they have been trained to detect, this will not mean that they will detect novel knives that have not been part of their training. The security concern raised by this finding is that actual threats will generally be novel tokens from outside the training set that has been used to prepare screeners, and so these actual threats may tend to be less well detected by screeners. This research illuminates the fundamental nature and problem of threat detection, and it has profound and sobering implications for applied security domains.

David's sharpest interest remains comparative-cognition research, as he seeks the earliest roots of human cognitive capacities like metacognition and prototype formation. In this search, given his training, he takes a distinctive theoretical perspective on comparative psychology that is an

intrinsically important part of his biography. He has seen that cognitive psychology has served itself generously in growth and insight for 40 years by taking: (1) a systems perspective that differentiates different levels and characters of cognition in mind, and (2) a neuroscience perspective that grounds these different learning processes in distributed brain processes. David believes that comparative psychology will also reward itself generously if it begins to adopt related approaches more broadly and systematically (Smith and Church 2017).

At present, David is exploring ways to unplug and disable humans' and animals' associative-learning processes, so that their parallel explicit learning processes – when and if these exist – can be studied clearly in isolation for the first time. David and others have clearly demonstrated qualitative dissociations of this kind with human participants using a variety of methodologies. In David's view, these approaches are good examples of the systems approach that should naturally be applied across species as well. They have the potential to open new empirical approaches to many areas of comparative research.

David's research has been supported by funding from the National Science Foundation, the National Institutes of Health, the European Science Foundation, and the Federal Aviation Administration and Transportation Security Administration. His research has been featured in numerous places, including *NPR*, *New Scientist*, the *Washington Post*, *Huffington Post*, the *Wall Street Journal*, and *US News and World Report*. He was elected President of the Southern Society for Philosophy and Psychology (2012). During more than two decades on the faculty of the Psychology Department at the University at Buffalo, SUNY, he collaborated with Language Research Center scientists to advance his studies of human and monkey cognition. In 2014, he joined those colleagues as part of the Department of Psychology at Georgia State University.

Throughout his career, David's primary pastime has been mountains and mountain climbing. One high point of many came when David summited Denali, the highest peak in North America, with just his one partner. A low point

came when David – with his young children – was caught by a freak hail and lightning storm above tree line on a difficult climbing path in the Alps. A point when time stood still came when David lost his way climbing down from 22,800 feet in the Andes. With his partner, he settled down at 21,000 feet enveloped by ice fog to wait through an endless night. But morning came, and the route down was revealed when saffron-robed monks appeared climbing toward them. David has climbed the Matterhorn, the Eiger, the Jungfrau, the Dent Blanche, Mt. Blanc, the North Face of the Tour Ronde, Denali, Aconcagua by its Polish Glacier route, and other peaks as well. His children sometimes will still go to the mountains with him.

## John James Audubon

Elaine M. Newbern and Elizabeth A. Forys  
Eckerd College, St. Petersburg, FL, USA

## Introduction

**John J. Audubon** was an ornithologist, painter, and conservationist most recognized for his contributions to the field of ornithology with North American species. He performed the first known American project with bird banding to study nesting behavior in birds. However, he is most remembered for his life-size magnum opus collections of drawings and paintings, *The Birds of America*, which included over 700 hand-colored, engraved copper plates depicting species in their natural habitat. Furthermore, his collection and its sequels, *The Ornithological Biographies*, have been considered some of the most noteworthy works completed in the field.

## Early Life and Background

Audubon was born on April 26, 1785, as Jean Rabin in the French colony of Saint Domingue (now Haiti). His mother, a chambermaid and mistress of his maritime father, died during his infancy from tropical disease (Rhodes 2004). Civil unrest regarding slavery in the Caribbean persuaded his father to return to France, after which he arranged for Jean and his half-sister to accompany him (Rhodes 2004). In order to naturalize the children as French citizens, they were legally adopted by their father and his French wife from prior to Saint Domingue. Additionally, they received name changes, with Jean's becoming Jean-Jacques Fougère Audubon (Rhodes 2004).

In his youth, Audubon excelled in many skills including music, dance, fencing, riding, and hunting. Among his other pastimes, his father fostered his love and curiosity for nature, most notably with birds (Burroughs 1902). At the age of 12 Audubon was enrolled in military school to eventually join the navy at the urging of his father (Rhodes 2004). This maritime path was averted, as his naval career was short lived due to his seasickness, distaste of naval studies, and failing his qualifications tests (Audubon et al. 1868).

He immigrated to the United States in 1803 at the age of 18, and anglicized his name to the familiar John James Audubon (Rhodes 2004). He took over a farm his father had previously purchased in PA called Mill Grove which held lead mines and the potential to be profitable (Audubon et al. 1899). It was at Mill Grove where his ornithological career began regarding his depicting birds in their natural habitats and recording their behavior, where he improved his taxidermy skills, and where he met his future wife (Audubon et al. 1899). However, after determining that the mines were too great of a pecuniary risk, Audubon sold part of Mill Grove and journeyed to NY to study new business trades in order to support his marriage (Audubon et al. 1899).

After moving to Louisville, KY, in 1808, Audubon married Lucy Bakewell and began a family including two sons and two daughters. Unfortunately, both girls died before the age of

two (Audubon et al. 1899). Audubon's newfound trade business in Kentucky struggled following President Jefferson's embargo placed on British trade (Rhodes 2004). This hardship prompted his moves to Henderson, KY, and then later to Ste. Genevieve, MO, before deciding to eventually terminate his business partnership in 1811 in pursuit of his ornithological and artistic career (Audubon 1826).

In 1812 he returned to KY from a trip to discover his collection of over 200 works of art had been eaten by rats. This left Audubon wracked with depression for weeks before resolving to recreate his entire lost collection at a higher standard (Rhodes 2004). Still struggling to provide for his family, he became business partners with his wife's brother. Their stability improved until the Panic of 1819 which left Audubon bankrupt and temporarily jailed for his debt, with his main income coming primarily from death-bed portraits and other sketches (Rhodes 2004).

## Bird Banding

In 1804 while at Mill Grove, Audubon performed the first recorded experiment with bird banding in America by testing if phoebes returned to the same nesting locations annually (Rhodes 2004). He secured light threads to the legs of nestlings just prior to them leaving the nest. These bands were loose enough not to cause the birds harm, but were fastened so that the birds could not remove the threads themselves. He then noted when the birds departed and recorded when some of the phoebes returned with the thread still attached the following spring. His continued study of the phoebes in this particular location ended after one of the farm's workers killed several of the birds to use as fish bait (Rhodes 2004).

## Vulture Study

Audubon studied feeding behavior in both black and turkey vultures in 1826 through a set of experiments in which he tested to see if vultures

scavenged with their sense of sight, smell, or both (Audubon 1835). He first began by hiding rotten meat behind pieces of paper with caged vultures nearby, only to have it go unnoticed by the birds. His experiment then entailed leaving a foam stuffed deer decoy in an open, visible area which was investigated by uncaged birds. In his final trial, he hid a fragrant deer carcass out of sight, and no birds were able to find it (Strycker 2014). After this experiment, despite poor experimental methods and flawed results, he published a paper on his work stating that vultures discovered food by sight rather than smell, nor a combination of the two (Audubon 1835). The paper, "Account of the Habits of the Turkey Buzzard, Particularly with the View of Exploding the Opinion Generally Entertained by Its Extraordinary Power of Smelling," was ridiculed by the public and fellow scientists. His findings elicited additional studies and opinions regarding the buzzards, including work from his colleague and friend Rev. John Bachman and the young Charles Darwin (Strycker 2014).

## Professional Career

Following a brief job as a taxidermist at a Cincinnati museum, he set out in 1820 to create a portfolio containing all of the birds in North America (Burroughs 1902). He hoped his prospective publication could surpass the level of artistic renderings done by fellow American ornithologist, Alexander Wilson. Beginning by traveling south, Audubon picked up side jobs including giving drawing lessons, selling or trading drawings for goods, and doing charcoal portraits upon request (Burroughs 1902). However, being away from his family for months at a time left his wife as the primary breadwinner with her job as a teacher (Rhodes 2004).

The content of Audubon's work was based on considerable field research and detailed note-taking while observing birds and other species (Audubon 1831). His typical process included extensive observation before killing a species, particularly if it was a newfound one, which was

quickly followed by hanging the creature from wires and threads to pose them for his art (Rhodes 2004). Once the specimens were taken down, they were occasionally dissected for study before being cooked and eaten by the end of the evening (Riely 2011). Audubon strived to create works of art that displayed species in their most authentic natural habitat; he went at lengths to ensure the accuracy of his work with both artistic technique and scientific accuracy (Riely 2011). Details he aimed to demonstrate include nest structure or materials, contents such as eggs or juveniles, and background details like flora typical of their diet or what they used as resources. Natural predators of the subject in his work were also occasionally featured (Audubon 1826). Some of his work contained different subspecies, for example different kinds of woodpeckers, to illustrate minute differences in appearance. Audubon chose to pose and draw his subjects before doing any taxidermy work so the animals still held more of their natural posture, rather than being rigid (Rhodes 2004). Similarly, he would feature the same species repeatedly within a composition to display different angles and anatomical views of the subject he was illustrating.

With the increase in his established works, Audubon ventured to Philadelphia in 1824 seeking publication for his drawings, only to be rejected (Audubon et al. 1899). He did, however, receive recommendations to pursue support from European investors, and with his wife's encouragement went to England in 1826 with his portfolio featuring hundreds of drawings (Burroughs 1902). Funding from advance subscriptions, exhibitions, oil painting commissions, and selling animal hides raised enough money to begin publishing Audubon's first volume of *Birds of America* throughout Europe in the form of hand-colored, engraved copper plates (Audubon 1826). Upon his return to America in 1829, he was reunited with his family and continued growing his drawing collection (Audubon et al. 1899). In 1830 he was elected a Fellow of the American Academy of Arts and Sciences while working on his sequel, *Ornithological Biographies*, a collection of life histories of each species included

within his first work (Audubon 1831). Both compilations were published between 1827 and 1841 in five volumes. Audubon was able to make significant contributions regarding bird anatomy, distribution, and our understanding of their habitual behavior based on his field notes and journals. In addition to these records, he also detailed how palatable each species was (Riely 2011).

Between 1840 and 1844 Audubon published an octavo edition of his *Birds of America* featuring more than 65 new plates in the collection (Audubon 1826). In 1846, he released the first volume of the *Viviparous Quadrupeds in North America* in collaboration with his colleague Rev. John Bachman regarding scientific text and his sons with drawings (Audubon and Bachman 1846). Although still working on continuing his collection of drawings of mammals, Audubon's health began to deteriorate in 1848 after he suffered from a stroke while starting to display signs of dementia. In 1851 he passed away peacefully in NY at his family home (Rhodes 2004). Following his death, the second volume of the *Viviparous Quadrupeds of North America* was published with the majority of the drawing contributions included done by Audubon's son, John Woodhouse Audubon, and the scientific information contributed by Bachman (Rhodes 2004).

Audubon's collective work at the end of his life included five volumes of *The Birds of America* and five volumes of *Ornithological Biography*. He became a member of several prestigious scientific groups such as the American Academy of Arts and Sciences, the Royal Society of Edinburgh, the Linnaean Society, and the Royal Society of London (Rhodes 2004). He was one of the first American conservationists in response to his observations regarding declining populations of native species from human interference, and expressed his concern over this decline within his writing (Riely 2011). Throughout his lifetime he discovered 25 new species, as well as 12 subspecies (Rhodes 2004).

School of Psychology, University of Sussex, East  
Sussex, UK

### Synonyms

Coordinated joint engagement; Coordinated  
person-object orientation; Joint visual attention

### Introduction

*Joint attention* is the state of shared attention by two or more parties to an entity or event. Bakeman and Adamson (1984) defined “coordinated joint engagement” as a state in which the “infant is actively involved with and coordinates his or her attention to both another person and the object that person is involved with” (p. 1281). Thus, the core developmental milestone is the ability to simultaneously engage with both social partners and objects or entities in the world – this coordination develops in Western populations in the latter half of the first year of life and continues into the second year; while often taken as representative of all humans, it remains an open question whether these developmental patterns are culture-specific or universal. There is considerable contemporary debate over the kinds of activities that should be subsumed under the rubric of “joint attention.” In developmental psychology, joint attention has been studied with respect to three classes of behavior: *initiating behavior regulation* (IBR), *initiating joint attention* (IJA), *responding to joint attention* (RJA). Acts of IBR involve requests for object delivery – for example, pointing towards or reaching for an out-of-reach bottle, while alternating gaze between the bottle and a caregiver. Babies display RJA when they are able to follow a social partner’s gaze or pointing gestures to particular locations. When babies point to entities for reasons other than to request that a social partner deliver the indicated object to them, then they are said to display IJA. A majority

of contemporary researchers in developmental psychology include only RJA and IJA as examples of joint attention, arguing that these states of engagement differ from IBR in better predicting language development, in their apparent social orientation (often taken to contrast with the instrumental nature of IBR), and in their electrophysiological correlates (e.g., Vaughan Van Hecke et al. 2007). More inclusive definitions of joint attention include IBR as a facet of joint attention, based on the common behavioral constituents that characterize all three kinds of triadic engagement: an identifiable “topic” (the entity that forms the joint focus of attention), a directive gesture or cue (gaze or pointing), successive visual fixation of the entity and a social partner – these define a referential triangle, irrespective of whether the babies are apparently requesting an action on an entity or requesting an adult to share in emotional exchange about the entity (Bates et al. 1975). Even more inclusive definitions take IBR, IJA, and RJA as manifestations of joint attention and also such phenomena as *social referencing*, where babies use a parent’s emotional cues to regulate their own approach to novel objects, and *imitation*, which is often predicated on mutually attentive social partners jointly engaged on an activity in a coordinated manner (Leavens and Racine 2009). For many philosophers and developmental psychologists, joint attention implies the mutual awareness that two people are engaged in this state of shared attention; however, even proponents of this approach note that “knowing together” is difficult, if not impossible to objectively measure in any species, including humans (e.g., Carpenter and Call 2013). Here, we will review the evidence for various aspects of joint attention in humans and animals, with special reference to our nearest living relatives, the great apes (Hominidae).

### Joint Attention and Language Development

In developmental psychology, joint attention is considered a key mechanism for language acquisition in humans (Butterworth 2003). If a child

points to a dog and her caregiver turns to look at the dog, uttering the label, “doggie!” and turns back to face the child with a huge smile, this encourages the formation of an association between dogs (referents) and the verbal labels (symbols) for those dogs. Similarly, if a child can follow a caregiver’s point to an entity while the caregiver utters its label, this could also serve as a mechanism for grounding symbols in real-world entities. In longitudinal studies, many researchers have found predictive relationships between IJA and RJA and both concurrent and later language abilities (reviewed by Colonnese et al. 2010).

### Joint Attention Across Species

These triadic competencies that define joint attention in our species are not displayed by human children until well towards the end of their first year of life. The fact that joint attention is not displayed early in human development has fostered considerable debate over the species-specificity of joint attention, with vigorous contemporary debate over theoretical positions that range from (a) claims that joint attention implicates uniquely human social cognitive capacities to (b) arguments that it is a product of the effect of uniquely human environmental circumstances on generalized mammalian social orientations to (c) claims that the state of joint attention is a widely distributed mammalian characteristic.

### Initiating Behavior Regulation (IBR)

Human babies begin making requests with gestures long before they can speak (Butterworth 2003). Pointing-to-request is often the earliest-developing use of referential gestures. It is widely believed that IBR is cognitively or motivationally distinct from IJA. Unlike IJA, IBR is not a reliable predictor of language development, and is not clearly tied to frontal regions of the brain associated with executive control (Vaughan Van Hecke et al. 2007). However, in the first study to discriminate IBR from IJA by Bates et al. (1975), the

authors characterized both IBR and IJA as requests (albeit with a different terminology). In their characterization, IBR constituted the use of a social agent to obtain an object, whereas IJA was the use of an object to obtain attention from the social agent; thus, both IBR and IJA were seen to be examples of a common cognitive ability for means-ends reasoning.

In later years, it became clear that children with autism spectrum disorder displayed a specific deficit in IJA, whereas their IBR behavior was not affected (Baron-Cohen 1989). This widely replicated finding is a central pillar of the contemporary view that IJA reflects a capacity for reasoning about others’ minds or a motivation for social engagement that does not exist in other species. At present, it is unclear whether the relative lack of IJA in people with autism is a core cognitive concern or a motivational matter. If autism spectrum disorder is characterized by a lack of motivation for social engagement, then the apparent lack of appreciation of others as mental beings could simply be a secondary consequence of a primary difference in motivation – if people do not find social engagement rewarding, then they will not display IJA to seek such social attention (i.e., they will not display the communicative means to elicit the social ends). There is, however, wide agreement that IBR reflects means-ends reasoning and no compelling evidence that IBR is restricted to the human species.

It is now well-demonstrated that great apes in captivity, with no special training, will capture the attention of a human observer and point to entities (usually, but not always, desirable food) in apparent requests for delivery of the indicated entity (reviewed by Leavens and Racine 2009). They do not point to unreachable food in the absence of an observer, therefore, these deictic (directive) gestures are communicative in function – this is determined by filming the apes in the presence and absence of a human observer. Great apes wait to point or otherwise gesture when somebody is looking at them, demonstrating that they discriminate visual attention in others (Bodamer and Gardner 2002; Krause and Fouts 1997). Thus, IBR as it was first defined in human populations, by requestive pointing, is often displayed by apes

in captivity. Reports of IBR in wild populations are more controversial – begging behavior is very commonplace in feral populations of great apes, and involves a characteristic begging gesture being interposed by the begging individual into the line of sight of another individual who possesses desirable food, and this is a quintessential pattern of IBR (Bard 1992). To date, requestive pointing, however, has only been reported once in wild chimpanzees (Hobaiter et al. 2014).

## Responding to Joint Attention (RJA)

The ability to follow gaze and pointing cues develops gradually in humans. In the second half of the first year of life, babies will follow pointing cues and gaze cues to nearby objects that are already in their field of view. By about 18 months of age, babies are able to follow gaze and pointing gestures to specific targets located behind them (Butterworth 2003). Among nonhuman primates, it is well-demonstrated that monkeys and apes follow the gaze of their conspecifics. Despite this evidence, there is a widespread contemporary belief that apes have difficulty with RJA.

**The Object Choice Task.** One experimental paradigm that measures an individual's capacity with regard to RJA is the Object Choice Task (OCT). The OCT involves an experimenter baiting one of (usually) two or three opaque containers out of view of the subject, and then presenting a deictic cue, typically a gaze or pointing cue, to indicate to the subject in which of the containers the bait is located. Human infants are successful at following pointing cues from around 12 months of age (Behne et al. 2012) and gaze cues from around 14 months of age (Behne et al. 2005). OCT studies with nonhuman subjects have demonstrated that individuals from a number of species demonstrate an ability to follow pointing cues, including domestic pigs, African elephants, domestic goats, and bottle-nosed dolphins, although animals' sensitivity to gaze cues is, at present, far more variable, both within and between species. Many studies have shown domestic dogs to be adept at passing the OCT, and this has led some authors to propose a theory

of convergent evolution between humans and dogs that has equipped the latter with specialized socio-cognitive skills in comprehending human communicative cues (Hare and Tomasello 2004). In contrast, nonhuman primates' frequent poor performance on the task has led to the propagation of theories of a human-unique ability to comprehend deictic cues within the primates that led to the emergence of verbal communication in our species (Herrmann et al. 2007), which appears to conflict with findings of some nonhuman primates successfully passing the OCT under some conditions (Mulcahy and Call 2009; Lyn 2010).

Miklósi and Soproni (2006) highlighted the variation in procedural aspects of the OCT, for example, the range of different pointing cues that are presented across species, and demonstrate that such differences can elicit differing levels of performance from individuals of the same species. Specifically, their review demonstrated that the distance and temporal properties of pointing cues appear to either facilitate or constrain comprehension in a number of species. For example, great apes tested with a *static* point, where the experimenter is in the pointing position prior to the subject entering the test room and remains so until the subject has chosen one of the containers, performed at almost ceiling level when the distance between the experimenter's fingertip and the baited container was minimal, with a majority of below-chance performances when this distance was greater than 50 cm. It has further been suggested that disparities in the literature with regard to the performance of nonhuman primates could be better explained by methodological and procedural inconsistencies than by species-level ability. Lyn (2010) suggested that the apparent failure of nonhuman primates to comprehend human declarative cues on the OCT is not due to their evolutionary history, but may in fact be attributed to the tendency in the current literature to disregard environmental factors, specifically rearing history, in the experimental samples. Considering that RJA capacity is a developmental process in human infants that emerges following an intensive period of interaction and engagement with human adults, with frequent exposure to deictic cues, it is important to consider nonhuman

subjects' experiential history with humans before drawing species-wide conclusions about ability based on evolutionarily adaptive explanations. Illustration of this point comes from Lyn et al. (2010) findings that apes raised in an environment rich in human interaction with intensive exposure to sociolinguistic engagement (so-called enculturated apes) significantly outperformed on the OCT apes raised in a more impoverished, institutional environment where interaction with humans was limited to daily husbandry tasks.

Mulcahy and Hedge (2012) highlighted further procedural inconsistencies in the OCT literature, noting that apes are typically tested with a *central* version of the task, in which the containers are in the direct line of vision of the subject, compared with a number of other species, including domestic dogs, who tend to be tested with a *peripheral* version, in which the containers are placed widely apart. They argued that in the *central* version, the salience of the containers, in which the subject is aware that a food reward is hidden, may override the salience of the cue presented, and this, combined with an increased implied effort in retrieving the reward in the *peripheral* version may inadvertently disadvantage the apes. In fact, the authors report that in the minority of studies in which apes are tested with a *peripheral* version, their performance levels are greatly increased. It is thus important to take into account these incommensurate sampling and testing protocols when discussing species' relative abilities with regard to RJA. As Leavens and Racine (2009) noted, "[b]ecause so many apes . . . clearly do follow pointing gestures, *given adequate experience*, failures to follow pointing are not diagnostic of any cognitive implication beyond a lack of either motivation or sufficient task-relevant experience to use the gesture" (pp. 254–255, fn. 5, emphasis in original). Table 1 lists 43 individual great apes who have passed the OCT.

## Initiating Joint Attention (IJA)

IJA is defined as pointing to "comment" or to "inform" another about the state of the world. In the original formulation of IJA in human children,

Bates and her colleagues (1975) described a developmental sequence of exhibition of self, offering objects to another, giving objects to another, and, finally, pointing to objects in apparent attempts to elicit infant-directed emotional engagement. Viewed in this way, exhibition of self is a commonplace behavior in both captive and wild great apes. For example, chimpanzees will overtly offer part of their body to another seeking tickles or grooming at that site (Bard et al. 2014). Wild chimpanzees have been reported to scratch at the site on their own bodies at which they seek to have another chimpanzee concentrate its grooming activities (Pika and Mitani 2006). Great apes exhibit frequent "displays" that seem to function to draw attention to the self; from the standpoint of the exhibition of self, it seems clear that this aspect of IJA, presentation of oneself to others, is widely shared among great apes (reviewed by Leavens and Racine 2009).

However, the use of pointing to direct attention to a distal event or entity of interest is less frequently observed in humans' nearest living relatives, the great apes. Notably, however, the two existing reports of pointing by wild apes (a bonobo, Veà and Sabater-Pi 1998, and a chimpanzee, Hobaiter et al. 2014) described pointing as part of a sequence of IJA. In the report by Veà & Sabater-Pi, a bonobo noticed the observers behind some foliage and pointed twice at the humans, while looking back and forth between the observers and the rest of his troop. Hobaiter et al. reported that a juvenile chimpanzee seemed startled by something after peering into Hobaiter's camera lens, then retreated rapidly towards her mother, pointing towards the camera while turning to look at her mother. In captivity, IJA has been reported in "enculturated" apes by Carpenter et al. (1995); Pedersen et al. (2009); and Lyn et al. (2011). More generally, virtually all of the ape language training projects involve tests of language comprehension in which the animals must choose a correct response by pointing to or otherwise selecting the correct referent ("X") when challenged with a question of the form, "Where is X?" (reviewed by Leavens and Bard 2011). These kinds of informative gestures are usually

| <b>Gorillas (<i>Gorilla gorilla</i> spp.)</b> |                               |
| Cola, Caroline, Zoe, and Dian                 | Peignot and Anderson (1999)   |
| <b>Orangutans (<i>Pongo</i> sp.)</b>          |                               |
| Chantek                                       | Tomasello et al. (1997)       |
| Sakura                                        | Itakura and Tanaka (1998)     |

<sup>a</sup>Note that considerable variation occurs between studies in procedures administered (Lyn 2010; Mulcahy and Hedge 2012) and often multiple cue conditions are administered within a given study; individuals named have passed some version of an OCT, but not necessarily discriminated all cue types provided to them

classified as examples of IJA when human children display them, but apparently not when animals perform informative actions (e.g., Carpenter and Call 2013). This double-standard of interpretation may contribute towards biased perceptions of the distribution of IJA among humans and their nearest living relatives, although few would

dispute that most humans, barring psychopathology, engage in joint attention at frequencies not matched in other great ape species. Thus, while humans may not uniquely display joint attention, they may display joint attention relatively more frequently than even language-trained or home-raised apes.

Conclusions

With respect to IBR, there is widespread agreement that great apes and other animals display this component of joint attention (Leavens and Racine 2009). Surprisingly, despite the high performances on the OCT by the dozens of apes listed in Table 1, there are numerous contemporary claims to the effect that great apes have difficulty with RJA (e.g., MacLean 2016); in fact, this is not consistent with the evidence, which suggests that apes have no particular difficulty in understanding communicative cues when they are given adequate experience with these signals (Leavens 2014, and see Table 1). Evidence for IJA in animals remains somewhat controversial; when such actions as exhibition of self are included in the definition of IJA, then there is substantial evidence that great apes display IJA in this sense, both in captivity and in the wild. Evidence for the use of pointing or other deictic gestures to draw attention to some distal entity, without also requesting it, is substantially more limited, but not nonexistent. Hence, every one of the components of joint attention typically studied in human children (IBR, RJA, IJA) has been displayed by great apes and other animals.

## Jonathon Crystal

Jonathon D. Crystal  
Department of Psychological and Brain Sciences,  
Indiana University, Bloomington, IN, USA

## Introduction

The objective of work in the laboratory of Jonathon Crystal is to develop animal models of memory, focusing on the types of memory that are impaired in human diseases. This work involves development of a range of models to evaluate elements of human memory in animals. For example, a number of techniques for evaluating cognition in rats have been developed, including binding of episodic memories (Crystal and Smith 2014), prospective memory (Wilson et al. 2013), what-where-when memory (Babb and Crystal 2006; Zhou and Crystal 2009), source memory (Crystal et al. 2013a), and retrieval

practice (Crystal et al. 2013b). These models can be applied to translational models of human diseases of memory, such as Alzheimer's disease.

## Biographical Information and Career History

Crystal was born and raised in Toronto, Ontario. He was an undergraduate at the University of Toronto, where he was fortunate to have two outstanding mentors, Ken Cheng and Sara J. Shettleworth. He spent almost 3 years in Ken's lab and a year in Sara's lab. He was also fortunate to publish articles with Ken (in 1993 in the *Journal of Experimental Psychology: Animal Behavior Processes*) and Sara (in 1994 in *Animal Learning & Behavior*), based on research he conducted as an undergraduate (including an honor's thesis conducted in Sara's lab). The Natural Sciences and Engineering Research Council of Canada (NSERC) provided Undergraduate Research Awards, which allowed him to spend three summers in the lab at "1 Spadina" (where Ken and Sara had their labs). The environment at 1 Spadina was outstanding for animal behavior and cognition (in addition to Ken and Sara, others included Jerry Hogan, David Sherry, and their grad students). Dave Brodbeck and Rob Hampton (grad students at 1 Spadina) were particularly influential for Crystal. Crystal received a Bachelor of Science degree from Toronto in 1992.

Crystal became interested in time perception from immersion in Ken's lab and courses offered by Sara and Ken. This interest led Crystal to attend Brown University for grad school and to work in the laboratory of Russell M. Church beginning in 1992. Crystal was fortunate to have Russ as an outstanding mentor in science, academics, and life. At Brown, Crystal focused on testing the hypothesis that timing is based on multiple endogenous oscillators. Crystal received 4 years of support from NSERC as a 1967 Science and Engineering Scholar at Brown. At Brown, he met his future wife, Andrea Hohmann, who was also a grad student in psychology. They were married in Providence RI in 1997. Crystal

received from Brown a Master's of Science in 1994 and a PhD in 1997. Part of Crystal's dissertation research was recognized by the New Investigator Research Award in Experimental Psychology (in 2000, from the American Psychological Association, Division 3).

In 1997, Crystal became an assistant professor of psychology at the College of William & Mary. In 1999, Crystal moved to the University of Georgia, where he and Andrea both took positions as assistant professors of psychology. In 2004, Crystal was promoted to associate professor, and in 2009 he was promoted to full professor. In 2010, Crystal and Hohmann moved to Indiana University, Department of Psychological & Brain Sciences. Other affiliations at Indiana University include the Program in Neuroscience, the Cognitive Science Program, and the Center for the Integrative Study of Animal Behavior. In 2013, Crystal became the Director of the Program in Neuroscience, a position that ends in 2018.

Crystal has served in a number of editorial roles. In 2016, Crystal became the Editor-in-Chief of *Learning & Behavior*, a position that ends in 2019. Earlier, he served as an Associate Editor of *Learning & Behavior* (2007–2015) and an Associate Editor of *Behavioural Processes* (2003–2007). Service on editorial boards include *Animal Cognition*, *Journal of Experimental Psychology: Animal Learning and Cognition*, *International Journal of Comparative Psychology*, *Comparative Cognition & Behavior Reviews*, and *Behavioural Processes*. Crystal was fortunate to serve as the Guest Editor of special issues of *Behavioral Processes* in honor of Russ Church (in 2007) and Tony Wright (in 2010, co-edited with Jeff Katz).

Crystal has also served in a number of leadership positions. In 2017, he serves as the President of the Society for Experimental Psychology and Cognitive Science (Division 3 of the American Psychological Association, a position that ends in 2018). He has a long-standing connection to the Comparative Cognition Society (President: 2010–2012. Secretary: 2006–2010. Executive committee member: since 2006. A founding member in 1999).

Crystal is a Fellow of the American Psychological Association (Division 3 in 2006 and Division 6 in 2011), the Association of Psychological Science (2007), the Psychonomic Society (2014), and the Eastern Psychological Association (2013).

## Contributions to Science

Crystal has made a number of contributions to science, as outlined below. A complete list of publications can be found at the National Library of Medicine:

<http://www.ncbi.nlm.nih.gov/sites/myncbi/jonathon.crystal.1/bibliography/40423670/public/?sort=date&direction=ascending>

## Animal Model of What-Where-when Memory

The Crystal lab developed and validated a rodent model of what-where-when memory. The field of research into episodic memory in nonhumans began with a prominent paper in *Nature* by Nicky Clayton and Tony Dickinson (using food-storing scrub jays) in 1998. Although a number of labs were initially unable to develop an analogue using other species (papers in 2002–2005), the Crystal lab developed a working model in rats (Babb and Crystal 2005, 2006). A major alternative to episodic memory (focusing on judgments of relative familiarity) was published in *Science* by Bill Roberts in 2008. The Crystal lab developed an approach to eliminate the relative familiarity alternative explanation, which was published in *PNAS* (Zhou and Crystal 2009). Subsequent work has used this later approach to the problem of familiarity. Although the question of episodic memory in nonhumans was initially controversial, this body of work is now widely accepted. The approach taken by the Crystal lab focuses on the content of episodic memory, not on any subjective experiences that are thought to accompany episodic memory in people.

## Animal Model of Source Memory

The Crystal lab developed the first evidence of source memory in a nonhuman (Crystal et al. 2013a). Source memory refers to memories about the conditions under which information was acquired. Episodic memory typically involves source memory because those memories focus on the origin of representations. Importantly, source memory allows us to differentiate one episodic memory from another because source memory includes features that were present when the memory was formed. This model has been validated and used to demonstrate that episodic memories are bound by the source features encoded with the episode (Crystal and Smith 2014).

## Animal Model of Prospective Memory

The Crystal lab developed the first evidence for prospective memory in a nonhuman (Wilson and Crystal 2012; Wilson et al. 2013). Prospective memory is the ability to remember to take some action in the future. Failure of prospective memory is a common feature of aging and negatively impacts both health and independence. Currently, the only other working model of prospective memory in nonhumans comes from research with nonhuman primates.

## Other Models of Memory

The Crystal lab developed a number of other animal models of memory. These models are integrative as research seeks to identify the elements of human memory that can be modeled in nonhumans. Compelling evidence for episodic memory in nonhumans comes from the demonstration that rats can answer an unexpected question after incidentally encoding information, an ability that requires a functioning hippocampus (Zhou et al. 2012). The Crystal lab showed that rats use episodic memory to remember multiple events (at least 30 items in context; Panoz-Brown et al.

2016). The Crystal lab also developed the first evidence for retrieval practice in a nonhuman (Crystal et al. 2013b) and independent working memory buffers (Bratch et al. 2016). Previously, the Crystal lab developed methods to assess meta-cognition in rats (Foote and Crystal 2007).

## Contributions to Timing Literature

Crystal's early work focused on testing the hypothesis that timing is based on multiple endogenous oscillators. This work integrated approaches from chronobiology with techniques from interval timing. This research program provided evidence that short-interval timing is based on endogenous oscillators with short periods (extending the reach of chronobiology) and that long intervals (below the limited range of circadian entrainment) can be timed (extending the reach of scalar timing into the range of hours, e.g., 3–16 h) (Crystal 2012).

## Collaborators

In addition to the influence of mentors (Cheng, Shettleworth, and Church), Crystal has been fortunate to have a range of other collaborators. He has benefited from talented graduate students (Matt Pizzo, Stephanie Babb, Allison Foote, Wenyi Zhou, George Wilson, Xan Smith, and Danielle Panoz-Brown) and undergrads (Aaron Ketzenberger, Xan Smith, Stefan Dalecki, and Alex Bratch). His lab has benefited from a small army of undergrads who have enabled the lab to explore memory using olfactory stimuli, many of whom are coauthors on papers from the lab (Bratch et al. 2016; Panoz-Brown et al. 2016). Collaborators at the University of Georgia include Ruth Furukawa, Marcus Fechheimer, and John Wagner, who provided opportunities to explore cognition in transgenic mouse models of Alzheimer's disease. Frequent collaborations with the Hohmann lab have opened outstanding new opportunities too numerous to list.

[Nonhuman primates](#); [University of St. Andrews](#);  
[Wolfgang Köhler Primate Research Center](#)

## Curriculum Vitae

Josep Call was born in Barcelona, Spain, and started to study psychology in 1986, with the aim to become a comparative psychologist and primatologist. After receiving his bachelor's degree in 1990 from the Universitat Autònoma de Barcelona, he moved to Emory University, Atlanta, USA, where he received a master's degree in psychology in 1995. Only 2 years later, in 1997, he finished his PhD on "The understanding of intentions and knowledge in orangutans, chimpanzees, and human children.

A comparative and developmental perspective” under the supervision of Prof. Michael Tomasello. He then started a lecturer position at the School of Biological Sciences at the University of Liverpool. In 1999, he moved to Leipzig, Germany, to work as a scientist at the newly founded Max Planck Institute for Evolutionary Anthropology in the Department of Developmental and Comparative Psychology. Together with Michael Tomasello, he established the associated Wolfgang Köhler Primate Research Center at the Zoo Leipzig and shortly after became the director of this center. In this unique research facility, which Josep Call and his colleagues designed especially for noninvasive behavioral studies with four species of nonhuman great apes (western lowland gorillas, Sumatran orangutans, bonobos, chimpanzees), he played a significant role in planning, conducting, and coordinating a range of research activities with nonhuman great apes. Since 2013, he is a professor in Evolutionary Origins of Mind at the School of Psychology and Neuroscience at the University of St Andrews, UK, where he is involved in establishing the Budongo Research Unit for chimpanzees at the Edinburgh Zoo.

Josep Call was the editor of the *Journal of Comparative Psychology* (2011-2017) and is member of numerous editorial boards of journals such as *Frontiers in Comparative Psychology*, *Primates*, *International Journal of Comparative Psychology*, *Learning and Behavior*, *Cognition*, and *Open Mind*. Furthermore, he is a member of the scientific committee of the Fyssen Foundation.

## Scientific Achievements

Josep Call is a comparative psychologist dedicated to exploring the cognitive skills and cultural processes of humans and other great apes to disentangle which of those are unique to the human species and which are shared with the other primates. His theoretical, empirical, and methodological contributions, groundbreaking findings, and numerous frequently cited publications have shaped the field of comparative psychology and our knowledge about the cognitive skills of other

primates. While he initially focused on nonhuman primates, he got increasingly less taxonomically centered and, in addition to great apes and human children, became interested in studying other non-primate species. With his enthusiasm for comparative psychology, he has nurtured a new generation of young scientists who continue to distribute his spirit and share the fascination for the cognitive skills of human and other animals.

His research has influenced different fields within psychology and the cognitive sciences, but also receives attention from the natural (e.g., biology) and social sciences (e.g., economics), as well as from engineering (robotics, artificial intelligence). According to Google Scholar January 2018, his work was cited almost 33,000 times, with approximately 2500–3000 annual citations, resulting in the h-index of 87 and the i10-index of 259. He has published almost 300 peer-reviewed articles, more than 40 book chapters, and several books (e.g., Call and Tomasello 2007; Call et al. 2017), including the seminal book *Primate Cognition* (Tomasello and Call 1997), which represents a milestone in the field of comparative cognition research and is still used as introductory literature and textbook for interested students and researchers.

From a theoretical perspective, Josep Call has enormously influenced the field of comparative cognition by proposing a new theory of primate cognition questioning the role of associative learning (Tomasello and Call 1997) and developing a revised view of theory of mind abilities in nonhuman primates (Call and Tomasello 2008). In addition he contributed to the development of the cultural intelligence hypothesis (Tomasello et al. 2005). Josep Call further invented new methods and tests to investigate, for example, metacognition, inferential reasoning, and inhibitory control in nonhuman animals, which were often applied for large-scale taxonomic comparisons (Call 2006; Amici et al. 2008). His signature papers report discoveries that have shaped the field of comparative cognition and inspired new lines of investigation. Among many others, his key findings are that dogs can learn verbal labels for objects by fast mapping (Kaminski et al. 2004) and that apes save tools for future use (Mulcahy

and Call 2006) and have robust long-term memories (Martin-Ordas et al. 2013). Only more recently, he achieved another breakthrough by demonstrating that nonhuman great apes can predict others' actions based on their goals and beliefs (Krupenye et al. 2016).

Josep Call has received several awards and acknowledgments for his research activities. Between 2005 and 2006, he was Fellow at the Zentrum für interdisziplinäre Forschung, Universität Bielefeld in Germany. Currently, he is Fellow of the American Psychological Association, USA (since 2013), and of the Cognitive Science Society (since 2015). In 2016, he has been elected Corresponding Fellow at the Royal Society of Edinburgh, which singled him out as being “one of the top scientists in the world in the field”, “involved in the highest calibre of scientific enquiry.”

## Joystick

William Whitham<sup>1</sup>, Michael J. Beran<sup>2</sup> and David A. Washburn<sup>3,4</sup>

<sup>1</sup>Georgia State University, Atlanta, GA, USA

<sup>2</sup>Department of Psychology and Language Research Center, Georgia State University, Atlanta, GA, USA

<sup>3</sup>Covenant College, Lookout Mountain, GA, USA

<sup>4</sup>Georgia State University and Covenant College, Atlanta, GA, USA

A joystick is any manner of computer hardware peripheral in which spatial deflections of a narrow cylinder cause accompanying, preprogrammed manipulations to stimuli on a connected

computer. Using a joystick, an experimentally savvy animal can navigate through [virtual] space, categorize stimuli, make decisions, and otherwise participate in any number of computerized cognitive-behavioral research tasks (Washburn et al. 1989).

By the 1980s in the United States, the relative availability and utility of home computers and gaming systems had made feasible psychological testing apparatus more complex than the operant levers and button boxes of experimental psychology's earlier history. However, although the experimental rigor afforded by home computers was equivalently useful to researchers of both human and animal psychologies, the mouse and keyboard apparatus that became standardized for use with the new technology was hyper-specified for human hands and brains. Adaptation of joystick technologies from the computer game industry for trained nonhuman animals allowed them to interface with the new technology and any software a creative psychologist could program. Some joystick-based apparatus, like the Language Research Center – Computerized Testing System that innovated the use of such technologies in comparative psychology, have seen use in hundreds of unique experimental designs (Richardson et al. 1990).

Joystick apparatus are most fruitfully used by animals with dexterous wrists and fingers and forward-facing eyes. Common species in the history of laboratory-based primate research, like chimpanzees (*Pan troglodytes*), bonobos (*Pan paniscus*), orangutans (*Pongo pygmaeus*), rhesus macaques (*Macaca mulatta*), and capuchin monkeys (genus *Sapajus*), have each proven prolific users of joysticks, as have some unexpected species such as rats and elephants (Hyatt 2013; Washburn et al. 2004). And, the use of joysticks fundamentally changed how primate cognition was viewed as the adaptation of computer testing was as profound a change as had been development of other apparatus such as the Wisconsin General Test Apparatus (Washburn et al. 2013).

In the past 10 years, touchscreens and tablets have become available to consumers to such degree that they now occupy much the same comparative testing niche that joysticks historically

have. Joysticks are less expensive, if only because the computer display and core components can be protected separately from the response apparatus. Joysticks also offer flexibility of response that is more easily attained by some animals (via the array of quick or sustained deflections that can be tracked at an arbitrary degree of precision) than the more motorically demanding taps, pinches, and swipes that touchscreens require. These advantages come at the cost of a steeper learning curve for both animal and psychologist, because the animal must first be trained with the joysticks and some programming skill will invariably be required of the psychologist for even the simplest of joystick/computer interactions. Joysticks also perhaps require an additional representational feat: an animal presented with a touchscreen need not understand the spatially discontinuous relationship between a floating stick in the hand and a set of pixels shaped like an insect on a nearby computer monitor, it just has to tap the bug! Joysticks, however, require overcoming the stimulus-response discontinuity problem that was a major limitation in early behavioral research using manual apparatus (McClearn and Harlow 1954; Murphy and Miller 1958; Stollnitz and Schrier 1962). However, with time and experience, numerous species learn to handle this discontinuity using joystick technology (e.g., Beran et al. 2007; Rumbaugh et al. 1989).

Just as operant chambers continue to exist alongside their would-be replacements, joysticks will likely continue to be used on their own merit and alongside touchscreens and other emerging apparatus into the future. Joysticks remain the superior response apparatus for tasks in which a high degree of response sensitivity is at a premium, like some mazes. In designs in which the entire suite of behaviors an animal produces during a trial can offer unique psychological insights, like mazes or metacognitive uncertainty tasks, joysticks are uniquely valuable in that hesitations and suboptimal responses are captured continuously. Even several decades after their initial adoption in comparative psychology, joysticks retain some unique strengths and untapped potential for furthering the study of animal cognition.

## Definition

There are numerous operational definitions of judgment bias. Combining definitions of Boleij et al. (2012) and Bateson and Nettle (2015), judgment bias is defined as follows (Roelofs et al. 2016, p. 2): A judgment bias is a relative reaction to an ambiguous stimulus, expressing an “interpretation” of this stimulus and an “expectation” of the consequences of the reaction (Boleij et al. 2012). In judgment bias tasks, “(...) animals that respond to the ambiguous stimuli similarly to the positive stimulus are interpreted as displaying a high expectation of reward in the presence of ambiguous information, and hence an ‘optimistic’ cognitive style indicative of a positive affective state. In contrast, animals that respond to the ambiguous stimuli similarly to the negative stimulus are interpreted as displaying a higher expectation of punishment or lower expectation of reward, and hence a more ‘pessimistic’ cognitive style

indicative of a more negative affective state” (Bateson and Nettle 2015, p. 3).

## Introduction

In its simplest explanation, judgment bias describes optimistic and pessimistic decisions made under ambiguity. It is a bias in the judgment of ambiguous information, influenced by emotional state. Thereby, ambiguous stimuli, which are not inherently positive or negative (i.e., which are affectively neutral), are interpreted in light of a current emotional state or mood. A negative emotional state, such as anxiety or depression, increases the likelihood of making a negative or pessimistic judgment of an ambiguous stimulus. A positive emotional state increases the likelihood of making a positive or optimistic judgment of an ambiguous stimulus.

Judgment bias is a form of cognitive bias, where emotional state influences cognitive processes (Mendl et al. 2009; Paul et al. 2005). Multiple cognitive processes are required for judgment bias to occur: a stimulus has to be registered by a sensory system, it has to be evaluated, and a response to the stimulus has to be decided on (Bateson 2016). It is as of yet unknown which of these components of decision-making under ambiguity are influenced by emotional state. That the process of decision-making under ambiguity as a whole is indeed influenced by emotional state has been shown by the many accounts of judgment bias following experimental manipulation of emotional state in both humans and animals.

## Measuring Judgment Bias in Animals

To measure judgment bias in an animal, it has to display a measurable expectation of either a relatively positive or a relatively negative outcome in response to an ambiguous stimulus. To achieve this, judgment bias paradigms for animals all contain several key elements (see Fig. 1). Animals are trained to discriminate between two reference stimuli, predicting either a positive or a negative outcome. The animal is trained to perform a

distinct behavior in response to each stimulus. After discrimination training, the animal is presented with ambiguous stimuli. Its responses to these stimuli can be interpreted as a measure of judgment bias. Harding et al. (2004) were the first to successfully apply such a paradigm to animals, using it to measure judgment bias in rats.

## Discrimination Training

During operant discrimination training, the animal learns to discriminate between a positive and a negative reference cue/stimulus. The animal will learn to associate the positive reference cue with a specific behavioral response and a positive outcome. The same goes for an association between a negative reference cue, a negative outcome, and another behavioral response. Reference cues used can be spatial (e.g., access to left or right arm of a radial arm maze), visual (e.g., different levels of color saturation), auditory (e.g., high- and low-frequency tones), olfactory (e.g., different odors), or tactile (e.g., coarse and fine sandpaper).

When training an animal to respond to these reference cues, either a go/no-go task or an active choice task can be used. In a go/no-go task, the animal has to perform a behavioral response when presented with the positive reference cue. When presented with the negative reference cue, this behavioral response has to be suppressed. For example, when the animal is presented with the positive cue, it has to approach a goal box to collect a food reward. When it is presented with the negative cue, approaching the goal box will result in a punishment. The distinction between a “go” response and a “no-go” response can be made by using a cut-off point, i.e., if an animal does not respond to the cue within a predetermined time period that starts with presenting the cue, a “no-go” response is scored. If it does respond within that period, a “go” response is scored. Alternatively, “no-go” responses can be distinguished from “go” responses when analysis of response latencies shows that the animal takes significantly longer to respond to the negative cue than to the positive cue. In an active choice task, an active behavioral response is required after both the positive and the negative reference cue. For example, when the animal is presented with

**Judgment Bias, Fig. 1** Example of a judgment bias test paradigm. The animal is trained to associate a positive reference stimulus/cue ( $S^+$ ) with a positive outcome and a specific behavioral response, and a negative reference stimulus/cue ( $S^-$ ) with a negative outcome and another specific behavioral response. During judgment bias testing, the animal's response to ambiguous stimuli is assessed. Here, reference stimuli used are auditory (1). A low-frequency tone predicts a large food reward (three chocolate candies) in a designated location (e.g., the left of two goal boxes). A high-frequency tone predicts a small food reward (one candy) in another designated location (e.g., the right of two goal boxes). During discrimination training, a correct response to a reference cue (approaching the appropriate goal box) is rewarded, while failing to show the correct response is punished by giving the animal a time

out and no food reward (2). After discrimination training, ambiguous stimuli that are intermediate between the reference cues are presented (here, tones of intermediate frequencies between  $S^+$  and  $S^-$ ). When the animal performs the behavioral response it associates with a positive outcome (approaching the left goal box), this is scored as an optimistic choice (2). When the animal performs the behavioral response it associates with a negative outcome (approaching the right goal box), this is scored as a pessimistic choice. Abbreviations:  $S^+$ , positive reference stimulus used in operant discrimination training preceding judgment bias testing, predicting a positive consequence;  $S^-$ , negative reference stimulus used in operant discrimination training preceding judgment bias testing, predicting a negative consequence

the positive cue, it has to push one of two available levers to gain access to a food reward. When it is presented with the negative cue, it has to press the other lever to avoid punishment. In contrast to go/no-go tasks, active choice paradigms allow the animal to refrain from choosing if it is unmotivated to do so. In go/no-go tasks, decreased motivation is always confounded with pessimistic choosing. When the animal does not respond, this is scored as a “no-go” instead of an omission.

To produce positive and negative associations with the reference cues, two possible reinforcement designs can be used:

1. Correct responses to the positive reference cue are rewarded, while incorrect responses to the negative reference cue are punished. The animal is trained to obtain a reward during positive trials and to avoid receiving punishment during negative trials. For example, in a go/no-go design, approaching the goal location is rewarded during positive trials, while negative trials should consist of a no-go response. Should the animal erroneously approach during a negative trial, it will be punished by exposure to a frightening stimulus (e.g., a loud noise).
2. Correct responses to the positive reference cue are rewarded with a highly preferred reward

(e.g., a large food reward in Fig. 1), while correct responses to the negative reference cue are rewarded with a less preferred reward (e.g., a smaller food reward in Fig. 1). The animal is trained to obtain rewards of different value during positive and negative trials. Incorrect performance leads to losing a chance of being rewarded. For example, in an active choice design, pressing one lever is required to obtain a reward during positive trials, while pressing another lever during negative trials will result in a less favorable reward (e.g., a smaller amount of food or a delayed reward).

Both reinforcement designs can be applied to either go/no-go or active choice paradigms. Over the course of multiple trials, animals are trained on the operant discrimination task. A predefined learning criterion is used to determine when discrimination training has been successful. For example, an animal can only proceed to judgment bias testing when it responds correctly to both the positive and the negative reference cue in 80% of its daily training trials.

### Judgment Bias Testing

Judgment bias testing can commence when an animal has successfully completed discrimination training. During judgment bias testing, ambiguous stimuli are introduced which are intermediate between the reference cues used during discrimination training. For example, when using a high- and low-frequency tone as reference cues, tones of intermediate frequencies can be used as ambiguous stimuli (Fig. 1). Often, multiple ambiguous stimuli are used, with varying levels of ambiguity. In addition to one ambiguous stimulus which is truly intermediate between the reference cues, “near-positive” and “near-negative” ambiguous stimuli can be presented, which have an increased similarity to the positive/negative reference cue. When presented with an ambiguous stimulus, the animal has to decide whether it considers this cue to be a predictor of the learned positive or negative outcome. Judgment bias can then be measured by recording the animal’s behavioral responses to the ambiguous cues. An animal can make an optimistic choice by performing the learned

response to the positive reference cue. A pessimistic choice can be made by performing the learned response to the negative reference cue (see Fig. 2 for examples of interpretation of go/no-go and active choice paradigms).

When an animal makes relatively more optimistic or pessimistic choices, this is taken as an indication of a more positive or negative emotional state, respectively. This is how judgment bias tasks can be used to compare (groups of) animals with assumed differences in emotional state. Similarly, the same animal(s) can be tested before and after experimental manipulation of emotional state. Judgment bias can be assessed in response to any of the ambiguous cues. In general, animals display a generalization gradient in response to the ambiguous cues, with the rate of optimistic choosing increasing as a cue’s similarity to the positive reference cue increases (Fig. 2). The shape of this response curve can differ for animals in a positive versus a negative emotional state, but also for animals experiencing different forms of negative emotions (Salmeto et al. 2011). For example, a negatively biased interpretation of the near-positive ambiguous cue indicates an animal has a decreased expectation of the positive outcome (i.e., decreased optimism). A negatively biased interpretation of the near-negative ambiguous cue indicates an animal as an increased expectation of the negative outcome (i.e., increased pessimism).

### Advantages of Judgment Bias Tasks for Animals

Judgment bias tasks for animals provide a cognitive measure of emotional state. As such, these tasks are useful in studies of animal welfare (Baciadonna and McElligott 2015; Bethell 2015) and studies using animal models of mood disorders. Measuring judgment bias can be a useful tool in assessing the effects of experimental manipulation of emotional state. For an animal welfare study, such manipulation could consist of barren versus enriched housing conditions. A biomedical study might assess the effects of mood enhancing drugs on judgment bias. An important advantage of judgment bias over other measures of animal emotion is that it provides a measure of the valence of emotional

**Judgment Bias, Fig. 2** Interpretation of judgment bias task results. Panel A: Time to approach plotted against cue type for an active choice task. Time to approach decreases as cues increase in similarity to the positive reference cue. When there is a positive judgment bias, approach times after ambiguous cue presentation will be faster compared to approach times for a negative judgment bias. Panel B: Likelihood of approach plotted against cue type for a go/no-go task. Likelihood of approach increases as cues

increase in similarity to the positive reference cue. When there is a positive judgment bias, the likelihood of approach after ambiguous cue presentation is higher than the likelihood of approach for a negative judgment bias. Note that measures of response latency and likelihood of responding can both be used in either an active choice or a go/no-go task. Abbreviations: Go/Go, active choice; S<sup>+</sup>, positive reference cue; S<sup>-</sup>, negative reference cue; intermed. betw., intermediate between

state. Other frequently used measures, such as heart rate or cortisol secretion, only provide a measure of emotional arousal. This distinction between positive and negative emotional state allows judgment bias studies to formulate clear hypotheses. Additionally, judgment bias tasks can provide a measurable indication of a positive emotional state. Such measures have been lacking in studies of animal emotion, where measures of negative emotion are much more numerous.

Another advantage of judgment bias tasks for animals is their applicability to a wide range of species. The different components of judgment bias paradigms (cues, reinforcers, and behavioral responses) can all be adjusted to suit the species to be tested. Reference and ambiguous cues can be chosen which are ecologically relevant and easily detectable. For example, a range of visual stimuli can be unsuitable for a species lacking a dependence on visual information in their everyday life. Reinforcers can be chosen which are distinguishable as positive and negative/less positive, while

having properties that are actually rewarding or aversive to the tested species. By applying such adjustments, judgment bias has now been successfully measured in species ranging from carpenter ants (d’Etorre et al. 2016) to bottlenose dolphins (Clegg et al. 2017).

### Limitations to Judgment Bias Tasks for Animals

Despite the potential of judgment bias tasks as a widely applicable test of animal emotional state, there are some limitations which have to be taken into account when designing judgment bias tasks and interpreting their results. The operant discrimination training that is required for judgment bias testing generally takes a considerable amount of time. Such extensive training can act as a form of cognitive enrichment and thereby be a confounding factor on test results. For example, the enjoyment of working for food rewards can offset any detrimental effects of experimental treatment on the animals’ emotional state.

Therefore, the training period prior to judgment bias testing can lead to a more positive emotional state than would be assumed based on experimental manipulation alone. This could lead to overestimation of effects of mood enhancing treatment, and detrimental effects of experimental treatment on emotional state could be underestimated or entirely absent from judgment bias results. To avoid a confounding influence of cognitive enrichment, the training schedule prior to judgment bias testing should be as short as possible. This can be facilitated by choosing appropriate reference cues which are easily distinguishable by the animal and requiring behavioral responses which are in the animal's natural behavioral repertoire.

During judgment bias testing, ambiguous trials are often not rewarded (Fig. 1). This can lead to animals learning to associate ambiguous cues with no reward over the course of the testing period. When this happens, ambiguous cues effectively lose their ambiguity, as they are now considered predictors of a specific (negative) outcome. Such loss of ambiguity during judgment bias testing can be another confounding factor. An association between ambiguous cues and a negative outcome (i.e., lack of reward) can lead to an increase in pessimistic choosing as judgment bias testing progresses (Doyle et al. 2010). This can lead to incorrect conclusions of a more negative emotional state. Therefore, it is important to prevent loss of ambiguity when designing a judgment bias paradigm. Most importantly, a lack of reward during judgment bias testing must not stand out as a negative outcome for the animals. This can be achieved by using a partial reinforcement schedule during discrimination training, allowing animals to become accustomed to occasional unrewarded trials (Düpján et al. 2017). To maintain responsiveness in spite of a lack of reward, secondary reinforcers can be used during training and testing.

A final common limitation inherent to judgment bias tasks for animals is the use of a learning criterion for discrimination training. Because only those animals are tested which reach the pre-defined learning criterion, results of judgment bias tasks can be biased towards animals capable of completing discrimination training.

Conclusions and recommendations based on such a subset of the studied population may not be generalizable to animals which could not reach the learning criterion. The more difficult the required operant discrimination task, the more animals will be excluded and the more biased the results of the judgment bias test will be. Therefore, it is important to ensure that the operant discrimination task is suitable for the species/group which is studied and that most, if not all, animals are able to master it.

## Conclusion

Judgment bias tasks for animals provide a cognitive measure of the valence of emotional state. A positive emotional state results in an optimistic interpretation of ambiguous stimuli, while a negative emotional state results in a pessimistic interpretation of ambiguous stimuli. Although there are some limitations to judgment bias measurements in animals that need to be taken into account, judgment bias can be successfully measured in a wide range of species.

## Kangaroo Method

Archana Singh<sup>1</sup>, M. Diravyaseelan<sup>1</sup> and Karthikeyan Pethusamy<sup>2</sup>

<sup>1</sup>Department of Biochemistry, All India Institute of Medical Sciences, New Delhi, India

<sup>2</sup>All India Institute of Medical Sciences (AIIMS), New Delhi, India

## Introduction

Kangaroo method of care or kangaroo mother care (KMC) is a special way of nurturing preterm and low birthweight babies (LBW) (Charpak et al. 2017). KMC was developed by a Columbian pediatrician, *Dr Edgar Ray* (Ruiz-Peláez et al. 2004).

## Components of KMC

KMC involves three components – kangaroo position (skin-to-skin contact), kangaroo nutrition (exclusive breastfeeding), and kangaroo discharge policies (early discharge in kangaroo position

regardless of weight or gestational age) (Charpak et al. 1996).

## The Need for KMC

Humans are endothermic/homeothermic animals. Temperature-regulating mechanism of human neonates, especially the premature and low birthweight ones is underdeveloped. So, these babies were usually kept in incubators to maintain their body temperature. This leads to separation of mother and baby-inducing stress in both mother and neonate leading to poor survival of the neonates and depression in mother which may later cause poor milk ejection reflex. Moreover, there is a shortage of incubators in developing countries, and KMC is a better alternative in this scenario.

## Administration of KMC

KMC can be started at birth and can be given continuously or in small sittings of not less than an hour. KMC can be given not only by the mother but also by the father or the grandparents. It should be started as earlier as possible to ensure maximum benefit for the baby.

While giving KMC the baby must be placed directly in contact with the chest, and the baby's head must be placed in between the two breasts in a frog position. The baby is held in position by a

soft fabric, and it should cover the baby until the shoulders. KMC is a skin-to-skin contact therapy; therefore there should not be any barrier between the caregiver and the child to ensure that there is a better therapeutic effect. There should be minimum or no discomfort while giving KMC. This therapy helps in enjoying the gift of motherhood for new mothers.

## Precautions During KMC

The person giving KMC must be seated in a quiet and calm environment. Parents must be preferably seated in a rocking chair wearing comfortable clothing. The parents must reduce their activity when the infant shows signs of distress, overstimulation. The caregiver must give enough time for the baby to feed and sleep without disturbance.

## Advantages of KMC

Due to constant skin-to-skin contact, KMC helps in constant thermal regulation and prevents the neonates from hypothermia. In low birthweight infants, there is better recovery and decreased chance of infection. So, KMC reduces mortality and morbidity in low birthweight infants (Conde-Agudelo et al. 2003).

Keeping mother and newborn in constant close contact makes the initiation of breastfeeding easier. Close contact with child establishes oxytocin and prolactin release in mother leading to formation and secretion of milk. When the child is given KMC, it helps the suckling reflex of the newborn, thus establishing a positive feedback cycle ensuring enough milk production for the baby.

The mother and the baby are under constant stress when they are separated. KMC reduces the stress and ensures better development and bonding with the mother (Charpak et al. 1996). The constant skin-to-skin contact facilitates the release of oxytocin in mother, which has a calming effect on the mother, and promotes bonding and affection with the newborn. This effect is further enhanced by prolactin release in mother; it makes her sleepy and relaxed. Thus, KMC

relieves the mother of postpartum stress (Cooijmans et al. 2017).

## Kanzi

Heidi Lyn and Beatrice Chenkin  
The University of Southern Mississippi, Long Beach, MS, USA

Kanzi is a bonobo (*Pan paniscus*) that fundamentally changed our understanding of nonhumans' capability to learn human language. The presence of language in humans and its presumed lack in all other animals had been one of the enduring assumptions of comparative psychology. The broad appeal of the presumption of the uniqueness

in human language is illustrated by centuries-old folklore from across the world about how people were given language, animals that had language, and/or people that could “talk” to animals. The assumption that language is unique to humanity was not even tested scientifically until the late 1800s (Furness 1916), but is definitely challenged by findings from Kanzi, and later participants in the studies at the Language Research Center of Georgia State University in Atlanta, Georgia.

Only since the 1960s have we successfully studied the language abilities of apes, our closest evolutionary relatives. This success was founded on the work of the Gardners (Gardner and Gardner 1969) who recognized that other efforts to teach apes to speak had failed because the focus was on verbal speech. In contrast, they trained their chimpanzee, Washoe, to use a form of American Sign Language. Later research detailed similar results with several other chimpanzees (Gardner et al. 1989) and even potential evidence of generational transmission of signing among the apes (Fouts et al. 1982). These paradigm-shifting results resulted in a wave of publications and sign language research projects with gorillas (Patterson 1978), Orangutans (Miles 1999), and other chimpanzees (Terrace 1979). Additional language projects with apes were inspired by the Gardners and included chimpanzee work with computer keyboards (Rumbaugh 1977; Savage-Rumbaugh 1986) and plastic symbols (Premack 1985). The field, however, was the focus of vicious criticism that alleged that much of the findings across all studies were founded on anthropomorphic over-interpretation and direct imitation of human caregivers by the apes (Sebeok and Rosenthal 1981; Terrace et al. 1979). The criticisms particularly focus on the idea that the apes had been trained to associate food with random “arm waving” (Pinker 1994) and that the strings of symbols produced by the apes in no way resembled syntactical sentences (Terrace et al. 1980).

## Early Findings

The bonobo language project began in the midst of this backdrop. Bonobos are very closely related to chimpanzees (in fact, they were previously

called pygmy chimpanzees), but these species have extremely different ecology and behaviors. Bonobos were considered to be potentially more intelligent, and certainly less aggressive, having a matriarchal social structure and a tendency to diffuse conflict with sexual interactions (de Waal 1989). Importantly, their physical structure was said to more closely resemble humans, leading to the hypothesis that their cognitive and communicative abilities were more human-like as well (Savage-Rumbaugh et al. 1985). In the early 1980s, the researchers at the Language Research Center borrowed Matata, an older female bonobo, from the Yerkes National Primate Research Center to take part in a language project in early 1981. Matata brought with her an adopted son, Kanzi, who was 6 months old when Matata began her training on the use of a computerized keyboard with abstract symbols (lexigrams) that represented objects, actions, and ideas (see Fig. 1). During this time, Matata was being conditioned to use the keyboard to obtain rewards, similar to the training that had taken place in previous language projects. Matata was guided to press a key on the keyboard, the English word was spoken, and the symbol lit up on a panel above the keys. Matata was then rewarded with the item she had chosen; however, Matata never consistently utilized any of the keys she was trained on (Savage-Rumbaugh 1986).

Kanzi was present for all of Matata’s training sessions, but was never the focus of the conditioning. If Kanzi used the keyboard, the caregivers would respond as they would to a human child – by speaking a response in English as well as using the keyboard. Kanzi would sometimes receive the items he requested, and other times would not. When Kanzi was 2 years old, Matata was sent back to Yerkes for breeding. The researchers prepared to begin training Kanzi. Instead, Kanzi began to use the keyboard on his own – even following up on his requests with gestures and body posturing toward the referents of the symbols he selected. He had learned the meanings of many of the keys before the first day of his training. Kanzi’s abilities were first reported in the book *Ape Language from Conditioned Response to Symbol* in which Savage-Rumbaugh et al. detailed his early learning and the novel testing

**Kanzi, Fig. 1** First page of the lexigram keyboard. The final keyboard comprised three panels of 128 symbols each. The third panel was added in the last few years of the Language Research Center study and was mostly syntactical and linking words (were, on, that, etc.). Early

versions were computerized and a key press would trigger a display of the lexigram and a repetition of the English word. Later versions were laminated paper that could be easily carried throughout the study area

paradigms that were created in order to establish his abilities scientifically (Savage-Rumbaugh 1986). His findings and those of his sister, Mulika, were then more thoroughly documented in 1986 (Savage-Rumbaugh et al. 1986). He was the first nonhuman primate to learn any aspect of human language in an observational and spontaneous manner (Hixon 1998; Sundberg 1996).

After this revelation, the researchers decided to re-think and re-invent Kanzi’s learning environment. Instead of providing incentives to Kanzi, his caretakers would simply talk to him and React to his attempts at communication as one would to a young child. When speaking to Kanzi in English, they would also activate the lexigrams that corresponded with their words, but gave no direct reinforcement. Kanzi’s language environment was expanded to the nearby 50-acre woods, in which specific foods had been placed in 17 different locations, all labeled by lexigrams (see Fig. 2). He was encouraged to use the keyboard to indicate the location he wanted to reach following demonstrations by experimenters. When the researchers would allow him, he would frequently

lead them to the location he had chosen. Kanzi also was engaged in many daily activities such as doing the laundry and preparing food – playing with toys and other bonobos, as well as games that were invented for him (a costumed bunny and gorilla that would sometimes be found in different areas of the property). While engaged all of these activities, Kanzi continued to learn and use the symbols on the keyboard appropriately.

One final surprise was in store for the researchers. As Savage-Rumbaugh et al. (1986) explain, one day a researcher mentioned that Kanzi seemed to be responding not just to the lexigrams, but to the English words that the experimenters used. Initially skeptical, Savage-Rumbaugh dismissed the accounts until one day when she mentioned the lights in the room (in English), and Kanzi immediately ran to the switch and began flicking the switch on and off (1986). Later tests confirmed that Kanzi could and did associate both the English word and the lexigram with the referent. This was the first time that nonhumans were shown to understand spoken English and the first time that nonhumans

K

**Kanzi, Fig. 2** Map of the woods locations at the LRC

had been shown to attach referential meaning to symbols without specific training. As such, Kanzi fundamentally changed the direction of the field.

### Reference

A subject frequently broached in the studies of animal language was whether they understand that symbols *refer to* external objects/actions/

locations or whether they have simply associated those symbols with getting those objects/actions/locations. To test external reference, researchers devised a double-blind testing procedure in which the symbols would be divorced from the rewards. In this procedure, Kanzi was presented a testing “booklet” – basically two boards that were hinged at the back. Testing items were arrayed on the bottom board, and the top was closed over the bottom – sandwiching the test array between the

boards. The boards were then handed to the experimenter (who did not know which items were in the test array). The experimenter would then ask Kanzi to indicate a specific item and open the booklet facing Kanzi, so he could respond by pointing to the corresponding picture or lexigram. The experimenter could ask in English – e.g., “Show me the apple” – or could show Kanzi a lexigram (or picture) above the test booklet. Kanzi, and later his sisters Mulika and Panbanisha as well as Panpanzee (a chimpanzee), scored well above average on these tests (Kanzi scored 178/185 on his first symbolic tests: 96.2% correct), indicating that they did associate the various symbols with the external objects (Savage-Rumbaugh 1986).

Further studies supported the idea that Kanzi (and the other apes who later came to the Language Research Center) had complicated knowledge of the symbols rather than the interpretation that had previously been argued – that the apes’ behavior was based on learning simple one-to-one associations between a symbol (button press, arm-wave) and an object (see Pinker 1994 for an example). An examination of the errors that the apes made on their vocabulary tests showed the same kinds of errors that humans make when speaking (Lyn 2007). Predominately categorical in nature, errors were also based on the sound of the English word, the physical representation of an object, and items that were frequently associated with each other (e.g., cereal and milk). This “web of associations” belies the idea that the symbols were nonmeaningful to the apes.

## Semantic Combinations

As there was continuing criticism regarding the syntactical abilities of apes, Savage-Rumbaugh and Lewin (1994) defined a few properties that a body of rules must meet in order to be designated as a “grammar.” The first several of these criterion are not specifically syntactic; rather they describe the semantic requirements underlying the organization of sequences. One such criterion is that each component must function independently. In

order to demonstrate this criterion, Greenfield and Savage-Rumbaugh (1993) tested whether Kanzi understood each individual word that he produced as part of a combination. Their analysis required that a word could only be considered a distinct element if it occurred spontaneously on 9 out of 10 occasions and if he responded with a corresponding behavior in 9 out of 10 subsequent occasions. As an example, if Kanzi requested a banana, he would be presented with an array of his favorite foods. Only if he then selected the banana from that array would “banana” be considered a communicative element. Eighty percent of Kanzi’s corpus met this criterion. Additionally, in other sessions, Kanzi would be asked to choose an appropriate lexigram (after hearing the English word) from an array. In these trials, the researcher was not aware of where the object was located. He successfully chose the correct lexigram in 73% percent of trials. In addition, Kanzi rarely repeated himself or produced semantically unrelated phrases, which suggests that the grammatical rules he used passed the second criterion for grammar which states that the combinations of words must be semantically related (Savage-Rumbaugh and Lewin 1994).

Another criterion for syntax is that there is a rule of relationships between two categories (Savage-Rumbaugh and Lewin 1994). In English, these rules are generally marked through word order. For example, usually the first word in a sentence is the agent of the action and the action follows as the second word – e.g., “Jim ran.” There are additional markers such as articles, prepositions, and cases, but the main syntactical rules in English are of word order. Therefore, “dog bites man” means something different than “man bites dog.” In several studies, Greenfield, Savage-Rumbaugh, and Lyn showed preferential word ordering in Kanzi and two other apes (Greenfield and Savage-Rumbaugh 1990; Lyn et al. 2011a).

In these studies, the apes’ utterances were coded into a number of semantic (as opposed to syntactic) categories: for example, agent, action, recipient, possessor. In early language learning, children’s two-word utterances most commonly fall into the categories of eight semantic combinations: agent-action, action-object, agent-object,

action-location, entity-location, possessor-possession, entity-attribute, and demonstrative-entity (Brown 1973). Seven of these relations were included in Kanzi's corpora, and 76% of his expressed relations fell into one of these categories. Other combinations included low-frequency semantic functions that did not fall into Brown's top eight semantic categories such as attribute of action. However, both still have semantic functions, they are just rarely combined. Panpanzee's (chimpanzee) and Panbanisha's (bonobo) utterances were also predominantly made up of the same semantic relation categories, with additions that were not found in Kanzi's corpora. For example, Panpanzee and Panbanisha would put an affirmative first and a goal, entity, or action second. This combination was also not copied from their caregivers, suggesting that the symbol ordering preference was created by the apes (Lyn et al. 2011a).

In those requests where both a lexigram and a gesture were included, semantic patterns were also observed. In these lexigram-gesture combinations, all three apes had a tendency to put the gesture last across a large range of semantic relations. Humans, on the other hand, most frequently put the gesture first in such combinations. Therefore, the development of this word-order strategy was independent of what had been demonstrated by their human caregivers. Word orders also varied depending on whether the phrase was produced using two gestures, as opposed to combinations of a lexigram with a gesture. For example, in action-goal combinations when only lexigrams were used, Panbanisha and Panpanzee would most frequently place the action word first (following the humans' preference), while in the lexigram-gesture combinations they would place the goal first (following Kanzi's preference). These changing preferences were characterized by Lyn et al. (2011a), as a potential proto-transformation – similar to the syntactical rules that switch word order preference depending on the sentence function (e.g., verb last, except in questions, in which case, verb first).

Both bonobos and chimpanzees combine semantic elements, but much less frequently than children. In addition, there is little evidence for

combinations based on syntactic categories (Noun vs. Verb).

## Syntactic Comprehension: Ape and Child

In a landmark study in 1993 designed to test whether apes could comprehend syntax, Kanzi's comprehension of English sentences was compared to that of a 2½ year old child, Alia (Savage-Rumbaugh et al. 1993). Alia was exposed to a very similar indoor environment to Kanzi – being raised half time at the Language Research Center, exploring the same wooded environment and using the lexigram keyboard with her mother and other experimenters. In the study, Kanzi and Alia were each presented (separately and with a double blind methodology) with several hundred English sentences and their responses to those sentences were recorded. Thirteen different request types and subtypes were presented to both (see Table 1). Each tested different semantic and syntactic capabilities.

Kanzi and Alia's success rates were similar (Kanzi was correct on 74% of blind trials, Alia on 65%). This was the first time an ape had shown language abilities that approached those of a human child. There were interesting differences in the errors made, however.

## Error Types: Alia and Kanzi

Both subjects rarely responded incorrectly to all sections of a phrase. For example, they would try to carry out an object with what they believed was the appropriate action, and in the case of those phrases with two objects, they rarely chose an incorrect object for both. The indication here is that they understood the overall structure of the sentence but not necessarily all the words. Alia exhibited more of a tendency to retrieve a variety of objects, only one of which would be the requested item. When Kanzi retrieved multiple items, it was most frequently under the circumstance where more than one of the requested object was present. When given the "announce information" sentence type, Alia would often

**Kanzi, Table 1** Sentence types for Kanzi and Alia. (Adapted from Savage-Rumbaugh and Lewin 1994)

| Type | Sentence form                                   | Example                                       |
|------|-------------------------------------------------|-----------------------------------------------|
| 1a   | Put object X in/on transportable object Y       | Put the ball on the pine needles              |
| 1b   | Put object X in nontransportable object Y       | Put the ice water in the potty                |
| 2a   | Give (or show) object X to animate A            | Give the lighter to rose                      |
| 2b   | Give object X and object Y to animate A         | Give the peas and the sweet potatoes to Kelly |
| 2c   | (Do) action A on animate A                      | Give rose a hug                               |
| 2d   | (Do) action A on animate A with object X        | Get rose with the snake                       |
| 3    | (Do) action A on object X (with object Y)       | Knife the sweet potato                        |
| 4    | Announce information                            | The surprise is hiding in the dishwasher      |
| 5a   | Take object X to location Y                     | Take the snake outdoors                       |
| 5b   | Go to location Y and get object X               | Go to the refrigerator and get a banana       |
| 5c   | Go get object X that's in location Y            | Go get the carrot that's in the microwave     |
| 6    | Make pretend animate A do action A on recipient | Make the doggie bite the snake                |
| 7    | All other sentence types                        |                                               |

state her own intent regardless of the request, which may indicate that she understood this form of phrase had a different function as the others. The most difficult types for both Alia and Kanzi were type 6 where they were requested to make a pretend animate A do an action A on a recipient Y (Savage-Rumbaugh et al. 1993).

One syntactical concept that some researchers believed was uniquely human is the ability to understand embedded sentences. To understand those phrases involves a comprehension of the fact that one word references a word previously presented in a sentence and that the second word changes the meaning of the first (Chomsky 1963). In the example “Go get the ball that’s outdoors,”

“Go get the ball” does not indicate the location in which the ball is located. When “That’s outdoors” is added, the meaning of the phrase changes to indicate the ball is located outdoors. Interestingly, however, Kanzi actually had more success in understanding these phrases, showing a success rate of 77% as opposed to Alia’s 52% (Lloyd 2004).

One argument surrounding the apes’ syntactical abilities as revealed by this study is the relative contribution of syntactical versus semantic knowledge. Researchers (e.g., Wynne 2008) argue that in many sentences, Kanzi (and Alia) could reliably complete the task with no syntactical knowledge at all. They argue that given reference (which was an earlier criticism, recall) and the words “PUT,” “KEY,” and “TABLE,” it would take no syntactical knowledge to correctly place the key on the table. There were a couple of reversible sentences in the study, on the order of “man bites dog” (e.g., “make the doggie bite the snake” (both toys) and “make the snake bite the doggie”), but these were a small proportion of the sentences tested (Wynne 2008). Evidence also does not suggest they understand embedded sentences, relative clauses, or subordinating constructions (Lyn et al. 2011a). However, a full exploration of these abilities has not been undertaken to date.

## Biology and Language

Kanzi’s abilities – and those of the other apes in the language program, have continued to re-shape the scientific understanding of what is unique about human language. For example, one of the first arguments to take shape after Kanzi spontaneously used the keyboard was that this was an ability humans shared only with bonobos. The second phase of the language project reared a bonobo (Panbanisha) and a chimpanzee (Panpanzee) together to specifically test this theory (Savage-Rumbaugh 1986). When the chimpanzee performed at a similar level to the bonobo, that myth was dismissed.

One concept that has been upheld is the concept of the critical period (early childhood) in which language is most easily learned. Two

bonobos that differed in age by only a year were compared. One (Panbanisha) was exposed to human language from the age of 7 weeks, the other (Tamuli) from the age of 3.5 years. For her infancy, Tamuli was mother-reared and only allowed contact with Panbanisha, Kanzi, and human caretakers sporadically. At 3.5 years, she was introduced to the same rearing methods as Panbanisha and Kanzi with the full range of lexigram exposure, English use, and activities. While Panbanisha and Kanzi were able to understand and use lexigrams very young in life, Tamuli did not successfully pass tests of lexigram comprehension even after her integration into the linguistically enriched environment. It seems as though, like humans, there is a critical exposure period related to the development of production and comprehension of language (Williams et al. 1997).

## Declarative Communication

Another concept put forward as the marker of human communicative uniqueness is declarative communication. It has been argued that apes only use imperative (request-based) communication, based on research studies in chimpanzees in which they failed to comprehend declarative pointing (Tomasello 2006).

One hypothesis that attempts to explain this deficit states that because chimpanzees tend to live in competitive, as opposed to cooperative, social groups, they do not respond or use declarative communication, which relies on cooperative motives. This hypothesis was tested by using an object choice task: a human would point towards one of two objects; the one that had the reward hidden inside. This object choice task was modified to compare competitive and cooperative gestures, and the chimpanzees performed better when the gesture was competitive (Hare and Tomasello 2004).

While declarative utterances were less frequent than requests, all three apes in the language program made thousands of declarative utterances (Lyn et al. 2011b). These utterances were compared directly to those of two children in the one-

word stage, and similar type of functional declaratives were found in children and apes. Apes also named objects that were already in their possession, indicating that they were not merely attempting to acquire the object (Lyn et al. 2011b).

More importantly, apes that were reared in the language environment outperformed typical research apes in the same object choice task that was used to spark the competition hypothesis (Lyn et al. 2010). It seems as if the key difference is not a biological capacity capability, but of a quantitative difference triggered by early environment – most specifically interaction with humans (Leavens and Bard 2011; Lyn 2010; Lyn et al. 2010).

## Other Skills/Studies

Kanzi has also been tested in his ability to make and use tools by anthropologists Kathy Schick and Nick Toth (e.g., Schick et al. 1999). The initial study showed that Kanzi could use a human-flaked stone knife to cut through a rope holding closed a puzzle box, with only one demonstration of a human using a similar knife. By the end of the first day, Kanzi consistently used a human-made flake of stone to cut the rope and was later able to differentiate between sharp stones and regular stones. Finally, Kanzi was given only nonshaped stones. After 25 exposures however, Kanzi was able to break apart the rock, detach a flake, and cut the cord that held the box closed. Following his first successful tool production, Kanzi formed his own tool on 15 occasions across a 75-day period. He had used both his own methods and those of his demonstrators to create the most productive method of opening the device, suggesting that bonobos were biologically capable of producing and using stone tools (Schick et al. 1999; Savage-Rumbaugh and Lewin 1994).

In 2004, Kanzi was re-located to Des Moines, Iowa, to the Great Ape Trust (also sometimes called the Iowa Primate Learning Sanctuary). He continues to be an active participant in research at the facility, since 2015 operating under the name of The Ape Cognition and Conservation Initiative (ACCI).

## Karen Hollis

Karen L. Hollis  
Mount Holyoke College, South Hadley,  
MA, USA

**Karen L. Hollis** was born on January 21, 1948, in Pittsburgh, Pennsylvania, to Norman E. Hollis, a partially self-taught industrial engineer with Screw and Bolt Corporation of America (now Ampco-Pittsburgh Corporation) and Clara Kammermeier Hollis, whose parents had immigrated to Pittsburgh from Germany. Hollis was educated in local parish schools and, inspired by a gifted mathematics teacher while in High School, a Franciscan nun, decided to enter

Slippery Rock State College (now Slippery Rock University of Pennsylvania) as a mathematics major. Although Hollis' father had taken several mathematics college courses in Pittsburgh, neither of her parents had college degrees. Indeed, her mother was the first in her family to graduate from high school. While at Slippery Rock, Hollis became greatly interested in a fledgling experimental psychology program chaired by a recent Ph.D. student of Herbert Kimmel, namely, William E. (Bill) Kirk, who mentored Hollis, convincing her to apply to graduate programs in experimental psychology. Hollis graduated with a B.A. from Slippery Rock State College in 1969 and entered the University of Minnesota the following year. Hollis' undergraduate participation in Kirk's classical conditioning research led her to University of Minnesota researcher J. Bruce Overmier, who became her Ph.D. advisor. Overmier was deeply committed to his students, and his mentorship was critical to her subsequent success as a researcher and professional academic. As she wrote in the acknowledgements of her Ph.D. thesis, a study of the role of the telencephalon in both classically conditioned and instrumentally conditioned species-specific behavior of *Betta splendens* fish, Overmier "expended more effort taking care of [his students'] careers than, frequently, they did themselves." Overmier never stopped doing so and continued his mentorship for the remainder of her career. He steered Hollis toward a 2-year research and teaching internship at the University of Toronto, where Hollis worked in the laboratory of Sara Shettleworth and taught one of the many sections of Toronto's introductory psychology course. Although that internship initially was planned to follow her graduation from the University of Minnesota, Hollis finished analyzing her thesis data while in Toronto, obtaining the Ph.D. in 1979 and the Richard M. Elliott Most Outstanding Dissertation, 1975–1979, from the Department of Psychology. Continuing to follow her interest in species-specific behavior, Hollis joined the Animal Behavior Research Group at the University of Oxford, under the direction of David McFarland.

While at Oxford, where the relatively new field of behavioral ecology was having a profound

influence on all aspects of the study of animal behavior, Hollis began working on two related projects, a theoretical review revealing the ubiquity of classically conditioned responses serving animals' reproductive success (Hollis 1982) and an experimental study demonstrating the biological function of classical conditioning that she began to formulate in graduate school (Hollis 1984). As she described many years later in an interview published in Lee Alan Dugatkin's text, "Principles of Animal Behavior, 2nd, 3rd and 4th ed." (2004, 2009, 2017), Hollis' thesis work afforded her a serendipitous observation of aggressive behavior, one that provided the raw material for years of subsequent research and shaped the rest of her career:

My project required me to transport each *Betta* male in its home tank to another room where it would have the opportunity to display to a rival. After a few days of this procedure, I noticed that when I approached the shelf on which the males were located and reached for a particular male's tank, it became quite agitated. After a few more days, each male that I selected began to display – at me! And, at eye level that display looked pretty ferocious! I recognized that some features of my appearance obviously had become a learned cue for the subsequent interaction with a territorial rival. At that time, associative learning in *B. splendens* already was well established (even if the experimenter-as-signal was a little unconventional). However, what was even more interesting to me was the realization that this kind of learning [i.e., classical conditioning] could be a wonderfully adaptive mechanism, providing a territory owner with a definitive competitive edge: Confronting a potential usurper with a full-blown aggressive display could be a very effective aggressive strategy for a territory owner. A few years later, as a postdoctoral student at Oxford, I had the opportunity to conduct those experiments with blue gouramis, *Trichogaster trichopterus*; and, as the data showed rather convincingly, the best defense is, indeed, a good offense.

Following her postdoctoral work at Oxford, Hollis returned to University of Toronto to accept a 1-year Visiting Assistant Professor position continuing her research and teaching the introductory psychology course. In 1982, she accepted a permanent position at Mount Holyoke College, a small liberal arts undergraduate institution in South Hadley, Massachusetts. Hollis remained at Mount Holyoke for the remainder of her career,

continuing her research on the adaptive value of classically conditioned behavior in blue gourami fish (and several other species), in both aggressive and reproductive contexts. For example, Hollis and her students showed how aggression in gouramis could be shaped by learned inhibition; how classically conditioned responses could have both short-term and long-term effects, the latter contributing to the phenomenon in which "winners become winners and losers stay losers" (Hollis et al. 1995); and how the ability to anticipate a rival enables subordinate fish to secure food using sneaky strategies (Hollis et al. 2004). A 1997 paper with her students, demonstrating how classically conditioned courtship displays provided male fish with paternity advantages (Hollis et al. 1997), was awarded Frank A. Beach Comparative Psychology Award "for the best paper published in *Journal of Comparative Psychology*, 1997."

Hollis was able to expand her research focus as a result of sabbaticals at the University of Cambridge and the National Institute of Biology in Ljubljana, Slovenia, the latter stay enabling her to switch species to insects. In 2007 she began a research collaboration with Elise Nowbahari, Ph.D., focusing on the predator-prey relationship between ants and larval antlions. Among their findings, Nowbahari and Hollis demonstrated the important role of rescue behavior in ants' ability to escape capture by antlions (Nowbahari et al. 2009; Hollis and Nowbahari 2013), as well as ants' ability to learn to avoid antlion pits (Hollis et al. 2017). On the other side of this predator-prey relationship, they demonstrated the role of learning in antlions' ability to obtain and process food efficiently (Hollis et al. 2011).

Hollis served as the head of the American Psychological Association's sixth division (Behavioral Neuroscience and Comparative Psychology) from 2006 to 2007 and the third division (Experimental Psychology) from 2010 to 2011. Hollis was the first woman to head both the third and sixth divisions. She has served on the editorial boards of several journals, including *Journal of Comparative Psychology*, *Animal Learning and Behavior*, *Psychonomic Bulletin*, and *Review and Behavioral Processes*, as well as Associate Editor of *Learning & Behavior* from 2002 to 2015. In

2016 Hollis was honored by the Comparative Cognition Society for her contributions to the study of animal cognition.

## Definition

A karyotype is the visual representation of the number and appearance of the complete set of

chromosomes in a species or in an individual organism.

## Introduction

Every other organism is characterized by a set of chromosomes to carry their genetic information. Karyotypes assess the chromosome count/ploidy of an organism and how they are visualized under a light microscope. It refers to a laboratory technique that depicts the image/photograph called as karyogram, in which the chromosomes have been arranged and sorted by size and position of centromere for chromosomes of the same size. Specific significance is given to their length, the position of their centromeres, any distinction between the sex chromosomes, and any other physical uniqueness. The significance of karyotype can be utilized for many purposes, to examine taxonomic relationship and past evolutionary events, to study chromosomal aberrations and cellular function. Nowadays, medical genetics has become increasingly integrated with clinical medicine leading karyotype to become a source of diagnostic information for certain birth defects, genetic disorders, and even cancers (O'Connor 2008).

## Understanding Karyotype

Humans have a total of 46 chromosomes, 23 from each parent which we can visualize in a karyogram. In a karyogram, homologous chromosomes or pairs of chromosomes that are of same size and shape are arranged together. Humans have 22 of these pairs called autosomes. Autosomes are chromosomes that have genes for everything but the determination of the sex. In humans, autosomes are numbered 1 through 22, having two for each. Chromosome 1 is the largest and chromosome 22 is the smallest. The remaining two chromosomes are the sex chromosome which determines a person's gender, male or female. They are placed after autosomes in a karyogram. The sex chromosomes are not numbered, but instead given letters X and Y. If someone has two X chromosomes, then they are

female. If someone has an X and a Y chromosome, then they are male (Swafford 2015).

## Preparing a Karyotype

A variety of tissue types can be used as a source of mitotic cells that have been arrested in their metaphase or prometaphase portion of the cell cycle to be used for karyotype analysis. For prenatal diagnosis, amniotic fluid is used as the source of cells. For cancer diagnosis, specific specimens include bone marrow samples or tumor biopsies and for other diagnoses, use of skin biopsies or peripheral blood samples is prompted. The process of generating a karyotype begins with the interim culture of cells isolated from a specimen. After the cells grow and multiply, dividing cells are detained in metaphase by addition of colchicine, which are spindle inhibitors. In metaphase stage of mitosis, chromosomes assume their most condensed conformations hence become visible under a light microscope. Therefore, almost all cytogenic work is done under metaphase stage. The cells are then treated with a hypotonic solution, which causes the cell to burst open and osmotic swelling of nuclei resulting in spreading of the chromosomes. The nuclei are then treated with a chemical fixative, and then slide is prepared by placing a drop of cell suspension followed by staining which reveals structural features of chromosomes (Fig. 1).

## Chromosome Staining-Banding Techniques

It is crucial to distinguish chromosomes from one another and group them accordingly to their size and the placement of their centromeres. Therefore, to make analysis more effective and proficient, cytologists have developed staining techniques that generate characteristic banding patterns for different chromosomes.

(a) **General techniques:** According to the study (Veerabhadrapa et al. 2016), certain human

**Karyotype, Fig. 1** Photographic representation of human chromosomes: male and female karyotype (<https://www.dreamstime.com/stock-illustration-male-female-karyotype-human-chromosomes-d-illustration-image98510413>)

K

chromosomes are distinguished on morphological grounds alone, for example, position of primary and secondary constrictions and length of chromosome arms. Autoradiography and aceto-orcin staining method can be used for studying morphology of chromosomes. Due to shortcomings, both are now replaced by banding techniques.

- (b) **Banding techniques:** In 1970, Torbjorn Caspersson and his colleagues described the first banding technique, known as Q-banding which involves the use of fluorescent dye quinacrine (O'Connor 2008). It was the first banding technique to stain all the human 46 chromosomes with quinacrine and visualize them under ultraviolet light. Q-banding is crucial for chromosomal translocations, especially ones including the Y chromosome. Others include, G (Giemsa) banding, R (Reverse) banding, C (centromeric heterochromatin) banding, T (telomeric) banding, and high resolution (fine) banding. Today, most karyotypes are stained with Giemsa dye in clinical cytogenetics, which though

produces same characteristic banding patterns as quinacrine but with more stable preparation and greater resolution and accuracy.

The base composition of DNA and local differences in chromatin structure are usually the molecular causes for staining differences along the length of a chromosome. In G-banding, prior to staining with Giemsa, metaphase chromosomes are initially treated briefly with a proteolytic enzyme, like trypsin (Veerabhadrapa et al. 2016). Trypsin denatures chromosomal proteins, hence relaxing chromatin configuration and allowing Giemsa dye access to the DNA. When the chromosomes are stained with Giemsa, G-bands appear on the light microscope. The G-bands constitute alternate light and dark bands, which reflect differential chromosome condensation. Heterochromatin regions (more condensed chromatin), with adenine and thymine-rich base pair region and few active genes, stain more darkly in contrast to euchromatin (less condensed chromatin), with guanine and cytosine-rich and higher active genes, giving light bands in G-banding.

G-banding generates reproducible patterns for each chromosome giving 400–800 bands distributed among 23 pairs of human chromosomes. Photographic presentation of the entire metaphase spread is taken and both homologs of each chromosome pair are arranged alongside in numerical order for precise analysis, which allows identification of delicate changes in banding patterns due to chromosomal abnormalities.

Other banding techniques, like R-banding, are also commonly used which generates the reverse pattern from G-banding. The chromosomes are subjected to heat treatment before Giemsa stain is applied. The heat treatment preferentially melts the DNA helix in the AT- rich regions that bind Giemsa stain most strongly, leaving the gene active GC-rich regions to take up the stain. This enhances analysis of small structural rearrangements in various parts of the genome which usually lead to phenotypic abnormalities. Another method is C-banding which specifically stains chromosomes at the centromeres rich in repetitive DNA sequences as well as constitutive heterochromatin. T-banding involves staining the telomeric (end) regions of the chromosomes and CT-banding which stains both the heterochromatin as well as the telomere of chromosomes to produce the CT- bands.

## Classification of Chromosomes for Karyotyping

As already mentioned, diagnostic information obtained from a chromosome preparation involving individual chromosomes is set in a standardized format known as a karyotype, or more precisely, a karyogram. Following international parameters, human autosomes or nonsex chromosomes are numbered 1 to 22, in descending order by size, exceptions are chromosome 21 and 22, followed by sex chromosomes.

Chromosomes are arranged into seven groups, based on size and centromere location (Veerabhadrapa et al. 2016). They can be categorized based on the position of centeromere; Metacentric chromosomes (center): chromosomes 1, 3, 16, acrocentric chromosomes (near one end):

chromosomes 13, 14, 15, 21, 22 and submetacentric chromosomes (slightly displaced from center): chromosomes 2, 6, 10. Chromosomes are aligned along a horizontal axis shared by their centromeres. According to the study (O'Connor 2008), individuals ones are depicted with their long q arms- q for “queue”- at the bottom and short p arms- p for “petite”- at the bottom.

Group A: Chromosomes 1–3 are the largest with median centromere.

Group B: Chromosomes 4–5 are large with submedian centromere.

Group C: Chromosomes 6–12 are medium-sized with submedian centromere.

Group D: Chromosomes 13–15 are medium-sized with acrocentric centromere.

Group E: Chromosomes 16–18 are short with median or submedian centromere.

Group F: Chromosomes 19–20 are short with median centromere.

Group G: Chromosomes 21–22 are very short with acrocentric centromere.

Chromosome X is similar to group C.

Chromosome Y is similar to group G.

## Application of Karyotype

In humans, majority of the genetic abnormalities are directly related to the chromosomal aberrations. Hence, karyotyping is extensively performed in the field of cytogenetics: (1) amniocentesis, to determine the sex of the child by observing the XX (female) or XY (male) chromosome pair and (2) aneuploidy, to check any deviation from the usual diploid or  $2n$  condition of chromosomes and translocations of tiny parts of chromosomes to one another. Since such procedures allow each pair of chromosomes to be notable individually, it has facilitated our understanding of the chromosomal basis of crucial genetic disorders. Researchers have utilized karyotyping procedure in prenatal diagnosis as well as neonatally discovered congenital abnormality and treatment of male infertility and screening in sperm donors to reduce birth defects (Xiao-bo et al. 2012).

refinements to Clark Hull's mathematical framework for understanding behavior. Although the two published together only once, the comprehensive perspective that they complementarily advocated is generally known as the Hull-Spence theory of learning. Hull himself acknowledged Spence's tremendous influence in numerous publications, including in his seminal text, *Principles of Behavior* (Hull 1943; see also Hilgard 1967; Kendler 1967). At the time of his death, Spence was one of the most highly cited and influential psychologists in the world. Kenneth Spence is also remembered as a prolific professor, responsible for directing 75 Ph.D. dissertations, primarily at the University of Iowa, where he served as head of the psychology department for 22 of the 26 years he was on faculty. At that time, it has been said that nearly every major psychology department in the United States included at least one former Spence student on its faculty (Wagner 2008). Consequently, Professor Spence's influence continues today through this academic legacy as well as through the scholarship he contributed to the literature.

Kenneth Wartinbee Spence (May 6, 1907 – January 12, 1967) was an American experimental psychologist and influential learning theorist, widely recognized for his systematic research on motivation. His research on conditioning and discrimination learning with rats, chimpanzees, and humans was reported in more than 100 journal articles and several books and guided his

## Personal History

Kenneth Spence was born in Chicago, Illinois to Mary E. (Wartinbee) and William James Spence. Kenneth would spend his childhood, adolescent, and early-adult years in Montreal, Canada, after his father, an electrical engineer, was transferred there in 1911 by Western Electric. Young Spence attended West Hill High School, where he excelled in basketball, tennis, bowling, and track. He subsequently enrolled at McGill University in Montreal, where he remained active in sports. However, a back injury sustained during a track meet would change the course of Kenneth Spence's career, to the considerable benefit of psychology. To recover from his injury, Spence moved to LaCrosse, Wisconsin to live with his grandmother. There, he attended the LaCrosse Teacher's College as a physical education major. It is not clear what sparked Spence's interest in psychology during this period – perhaps it was another serious sports injury he received

while there, which resulted in 6 weeks of hospitalization – but when he returned to McGill, he did so as a psychology student, although he continued to work as a YMCA basketball coach (Hilgard 1967). Spence earned Bachelor of Arts (1929) and Master of Arts (1930) degrees in psychology from McGill. In 1930, he coauthored the first of what would become many empirical papers (Spence and Townsend 1930), a so-called comparative study of the relation between intelligence and learning of a finger maze by 20 psychology undergraduates. The modest article – the authors themselves acknowledged, “The study was undertaken primarily with the view of gaining some knowledge of the technique and problems of experimental psychology, and not with the hope of being able to make any great contribution to psychology” (p. 113) – serves nevertheless to introduce the kind of meticulous attention to methodology and careful and detailed analysis of behavior that would characterize Spence’s subsequent and more impactful publications. A coauthored statistical publication (Kellogg and Spence 1931) would also result from his McGill research.

For graduate study, Spence attended Yale University, where he was clearly influenced by psychology professor Clark Hull. For example, Spence’s 1932 publication on maze-learning by rats was developed from a paper presented in a seminar taught by Professor Hull, in which Spence reanalyzed data from Tolman and Honzik (1930) from a Hullian perspective (Spence 1932). This article would be followed by other Hull-inspired studies of learning, as with the Spence and Shipley (1934) study of blind-alley maze-learning. Rats were tested on a maze with paths occluded by black curtains and demonstrated a strong orientation toward goal-pointing alleys instead of the nongoal-pointing alleys. Further analysis into individual alley error rates supported a Hullian goal-gradient hypothesis of maze learning.

However, Spence was not a “Hull student” in the formal sense. Rather, Spence worked as an assistant to Robert M. Yerkes while completing his graduate degree. His dissertation, completed

in 1933 under the direction of Yerkes, concluded that the visual acuity of a chimpanzee was comparable to that of adult and adolescent human subjects (Spence 1934). After earning his doctorate, Spence spent four postdoctoral years as a National Research Council Fellow at the Yerkes Laboratories of Primate Biology, in Orange Park, Florida. (Dr. Spence had applied for postdoctoral training in mathematics, reflecting his belief that psychological science must be expressed computationally; however, his fellowship application was denied because it was felt that a psychologist would not benefit from such training; Kimble 1998.) Many of Dr. Spence’s other early publications were studies of chimpanzee vision and discrimination learning, including some of his earliest attempts to investigate transposition, insight, and other Gestalt notions within an associative framework (e.g., Spence 1938, 1941).

In 1937, Spence moved to the University of Virginia for a 1-year replacement position, and subsequently accepted faculty appointment at the State University of Iowa, where he would spend the majority of his career. Already one of the most important psychology departments in the country, the University of Iowa (as it is now known) became a fountainhead of theoretical and neo-behaviorist psychology with Spence’s assistance and leadership.

Professor Spence also garnered individual accolades during this period. He was elected to the National Academy of Sciences and the Society for Experimental Psychologists and received the Howard Crosby Warren Medal from the Experimentalists in 1953. He was the first psychologist selected for the prestigious Silliman Memorial Lectures (1954), an honor awarded since 1901 generally to scholars from astronomy, chemistry, geology, anatomy, and other natural sciences. In 1956, Kenneth Spence was one of the three inaugural recipients (with Wolfgang Köhler and Carl Rogers) of the American Psychological Association Award for Distinguished Scientific Contributions to Psychology.

In his personal life, Spence married twice. While in LaCrosse, he met and married Isabel

Temte, with whom he had two children. After their divorce, Spence married Janet Taylor in 1960. In 1964, Kenneth and Janet Taylor Spence (who would emerge as one of the most important and influential psychologists in her own right) moved to Austin, Texas, where he joined the faculty at the University of Texas. Three years later, Professor Spence died from cancer at the age of 59.

## Contributions

Across his too-short career, Kenneth Spence combined rigorous methodological behaviorism with a neobehaviorist search for the mathematical relation between intervening variables, each carefully operationalized, that might describe, predict, and ultimately explain behavior in a comprehensive way. Through investigations of maze solving, discrimination learning, and eye-blink conditioning, Spence sought general principles regarding motivation and the effects on habit strength, or learning, of responses that serve to reduce these drives. His theoretical-experimental research not only refined his own version of the Hull-Spence framework but also provided significant empirical foundation for Hull's writings, often challenging the elder scholar to revise his theory so as to accommodate Spence's findings. It is said Hull added the intervening variable "incentive-motivation" to his hypothetico-deductive theory in response to his former student's arguments, and labeled the variable "K" in honor of Kenneth Spence.

A significant example of Spence's theoretical model was published just 3 years after he completed his Ph.D., in a formative review of discrimination learning in nonhuman animals (Spence 1936). Building on previous work by Lashley (1929) and Krechevsky (e.g., 1932), Spence attempted to account for systematic response biases that were demonstrated by nonhuman animals prior to learning. Arguing that discrimination learning involves changes in the excitatory and inhibitory tendencies of both task relevant and irrelevant stimulus characteristics, Spence

suggested that the prelearning behavior of a subject was not due to spontaneous hypothesis testing or insight, but offered instead a continuous learning, associative account – that an animal's pre-acquisition response pattern reflects the early stages of learning.

Twenty years later, Spence's theoretical model, and the decades of research behind it, was fully explained in *Behavior Theory and Conditioning* (1956), the volume that resulted from his Silliman lectures at Yale. In those essays, Spence summarized how his computational framework, derived to explain simple conditioning phenomena, can also explain more complex forms of behavior. Bruner (1957) praised the book as "at once modest in its scope and passionately grand in its aspirations" (p. 155).

In the final years of his life, Spence's research focus shifted from studies of nonhuman animals to conditioned eye-blink research with humans. For example, he examined the effects of anxiety on eyelid conditioning. Many of these studies were conducted in collaboration with Janet Taylor Spence, who is widely recognized as a leader in the study of anxiety. Kenneth and Janet Taylor Spence also worked together to edit *The Psychology of Learning and Motivation* series. These contributions to the understanding of human behavior are important, but it is also important to remember that these developments were richly informed by his earlier research with nonhuman animals.

Three years after Kenneth Spence died, Myers (1970) analyzed citation rates in the 14 most prestigious journals in psychology, together with other measures to produce a ranking of the most eminent psychologists. For the period of the review, Spence ranked #1 in citations and #8 in overall importance of all contemporary psychologists.

Additional evidence of Spence's eminence is found in his academic legacy. Supported by prolific publication of clever, systematic research and critical, integrative literature reviews discussed above, Spence trained a generation of disciples under his passionate and intimidating direction. In addition to supervising the doctoral projects of

75 students (four times the number supervised at Yale by Hull; Wagner 2008), Spence annually taught multiple graduate seminars on learning, courses were as rigorous and meticulous as were his published works (Amsel 1995; Wagner 2008). In contrast to the atheoretical Skinnerian behaviorism and the phenomenon-driven cognitive psychology that would follow, Spence's students were instructed and inspired to make contributions to psychology that advanced both data and theory. This was the lofty standard to which Spence held his mentees. This was the standard to which Kenneth Spence held himself.

## Ketone

Andrea R. Seitz<sup>2</sup> and Christine D. Calder<sup>1,2</sup>

<sup>1</sup>Mississippi State University, Starkville, MS, USA

<sup>2</sup>Mississippi State University, Mississippi State, MS, USA

### Definition

A ketone ( $\text{RC}(=\text{O})\text{R}'$ ) is a molecular compound composed of a carbonyl group bonded to two carbon-containing substituents. The symbols R and R' represent any alkyl group (Solomons 1978).

### Introduction

In chemistry, a functional group contains chemical elements that are bonded in a specific arrangement, which leads to specific chemical and physical properties. Important functional groups in physiological chemistry include alcohols, aldehydes, ketones, carboxylic acids, and amines (Harper et al. 1979). This entry will focus on the ketone, which has a role in animal physiology and pathophysiology.

### Naming Ketones

Ketones typically end in the suffix *-one*, and the ketone chain is numbered in which the carbonyl carbon receives the lowest number in the scheme. Ketones can also have common names, which are often derived by naming the two groups on either side of the carbonyl group and ending with the word ketone. Examples of ketones with their common names in parentheses include propanone (acetone), butanone (methyl ethyl ketone), and 2-pentanone (methyl propyl ketone) (Solomons 1978).

## Physical Properties

Although the carbonyl group of ketones gives rise to polarization and the formation of strong bonds to water between the carbonyl oxygen and the water hydrogen, ketones cannot form strong hydrogen bonds between one another (Solomons 1978). Also, the oxidation of ketones does not readily occur because oxidation would require an alkyl C–C bond to break in order for the ketone to lose a hydrogen atom. In contrast, ketones can undergo a reduction reaction, which results in the formation of a secondary alcohol. Ketones can also go through a condensation reaction to create  $\beta$ -hydroxyl acids, which demonstrate a role in fatty acid metabolism (Harper et al. 1979).

### Ketosis

When carbohydrates are depleted in the body and free fatty acids are mobilized, the liver oxidizes these fatty acids to produce ketone bodies as an energy source. This process is termed ketosis, and it can occur with many states, including during starvation, diabetes mellitus, pregnancy, and lactation (Harper et al. 1979). As pathological disorders occur, chemical changes also occur in the blood, urine, or milk of the affected animal. This is of great importance to the dairy cattle industry because as ketone bodies increase in a dairy cow, their milk production decreases. The ketone bodies of acetone, acetoacetate, and  $\beta$ -hydroxybutyrate can be measured in the blood and urine. For the dairy cattle industry,  $\beta$ -hydroxybutyrate in the blood is typically evaluated to determine if a dairy cow is in a ketotic state, which may be the cause for a decreased milk yield or other production or health-related problems (Overton et al. 2017).

### Conclusion

A ketone is a functional group in chemistry that contains a carbonyl group and two alkyl groups.

Ketones are an important chemical structure for the animal body to survive. Ketone bodies are created during fatty acid metabolism during times when the primary source of energy in the body, carbohydrates, is depleted. Ketone bodies can be measured in an animal to determine if ketosis is occurring and should subsequently be treated.

## Knockout Genes

Fayaz Ahmad Mir

School of Life Sciences, Jawaharlal Nehru University, New Delhi, India

Gene knockout (KO) is a genetic engineering method by which both the alleles of certain gene/genes are made inoperative/nonfunctional or deleted from the organism's genome. Knocking out a particular gene provides valuable information about functional role played by that gene and has proved as an effective method to study genetic basis of various diseases including cancer, diabetes, neurodegeneration, as well as aging. Gene knockout could be a “whole body knockout” if the particular gene is deleted from every cell of a multicellular organism or it could be a “conditional knockout” if the gene is deleted only in specific group of cells/tissues or from a particular organ. Gene knockout is one of the essential components of functional genomics whereby using homologous recombination or more recently clustered regularly interspaced short palindromic repeats (CRISPR), a mutated version of wild gene achieved by in vitro mutagenesis is exchanged with original gene to render it nonfunctional. More than 11,000 genes have been knocked out so far in mice accounting for half of the total genome in this most common laboratory animal (Vogel 2007). For the first time in 1989, Mario Capecchi, Martin Evans, and Oliver Smithies successfully created the world's first knockout mice and were jointly awarded Nobel Prize in Physiology and Medicine in 2007.

Gene targeting techniques including gene knockout by CRISPR/Cas9 systems are used to change the genomes of any living organisms. When a mutation is deliberately induced in a gene of interest for rendering it functionally inactive, it is called gene knockout (KO). Scientists use KO techniques to draw various inferences by observing the differences between normal individuals and KO models from the same species. Gene knockout approaches are used to classify a

particular gene function by inhibiting the gene of interest. Gene knockout is found both in classical genetics and in modern techniques such as functional genomics (Lin et al. 1984). The gene knockout was carried out during the initial time scale by transposon mutagenesis, but the major drawback of that approach was that it was laborious to screen out the knocked out gene. In vitro techniques are used to change genes on plasmids or bacterial artificial chromosomes (BACs), and then the cell culture techniques pass these modified constructs to the organism of interest. The best approach for creating a gene knockout is homologous recombination, and a single gene is deleted/inactivated by gene knockout techniques at a time, without affecting all the other genes in an organism. With the aid of such genetic engineering techniques for gene knockout, the resultant organism is known as “knockout” organism, where the gene of interest is inoperative unlike “gene knockdown” approach where the expression of an original gene of interest is inhibited by RNA interference technology without deleting the original gene. When more than one gene is knocked out in an organism then depending on the

number of genes, it is called double knockout or DKO, triple knockout or TKO, and quadruple knockouts or QKO, respectively. However, it is noteworthy to mention that when both the alleles of a gene are knocked out, it is called “homozygous KO,” but when only one of the alleles is deleted from the two alleles of a gene, it is called “heterozygous KO,” respectively.

## Strategies for Generating Gene-Knockout

Various basic and advanced genetic engineering strategies based on homologous recombination as well as site-specific recombination and engineering embryonic stem cells have been utilized to generate gene knockout organisms such as knockout mouse (Hall et al. 2009) (Fig. 1). Recently, some advanced methods like CRISPR/Cas9 as well as TALENs have also been used for the same purpose with more accuracy and maneuverability. Below are the most common and recent techniques used to achieve gene knockout organisms.

K

**Knockout Genes, Fig. 1** Site specific recombination for generation of gene-knockout mouse employing embryonic stem cells

### Site-Directed Mutagenesis and Gene Targeting in Embryonic Stem Cells (Homologous Recombination)

This method was pioneered during the late 1980s and one of the first techniques used in construction of whole-body gene knockout mice (Thomas and Capecchi 1987). This method is based on the principle of homologous recombination where a synthetic DNA sequence similar to the gene to be knocked out is altered in such a way that when it gets inserted at the place of original gene due to homologous recombination, this gene is rendered inactive. Additionally, this newly inserted and base sequence-altered DNA also contains a marker gene, usually an antibiotic resistance gene like neomycin resistance marker (NeoR) for killing nonrecombinant cells and only allowing recombinant ones to survive because of the ability conferred by marker gene. The vector DNA also contains a negative selection marker gene such as thymidine kinase (TK) which is derived from herpes simplex virus and is located outside the right arm of targeting vector. Normally, mouse cells are able to grow in the presence of an antiviral drug called ganciclovir. The TK gene is also called a “cell suicide gene,” but cells having the TK gene can convert ganciclovir to a potent toxin thereby killing the animal cell. This gene is used to screen the recombinant cells where the targeting vector has been properly inserted at the loci of “gene of interest” and not anywhere else non-specifically. In case of non-specific insertion of vector, the cells will be containing both the genes NeoR and TK which will kill cells when grown in the presence of ganciclovir drug. This site-directed mutagenesis and consequent integration of altered DNA in place of wild gene are achieved by the help of cre recombinase enzyme usually called as “Cre-Lox recombination” (Hall et al. 2009; Marth 1996). After designing the vector, the next step in the creation of gene knockout is delivering this targeting vector to embryonic stem cells of animal models such as mouse. Microinjection and electroporation are the most widely recognized strategies which are applied to transfer this DNA construct into the embryonic stem cells under in vitro culture conditions. The joining of vector

develop into target site relies upon the DNA repair mechanism of the organism’s cells or can be achieved by Cre-Lox recombination machinery. When incorporated, the vector component will bring about shift of wild-type gene and in the long run creation of nonfunctional protein and also inserting the markers in place of original gene. After this, the screened recombinant/knockout ES cells are injected into a developing embryo (blastocyst) so that these knockout ES cells will be a part of the growing embryo and may contribute to the formation of many organs in the fetus resulting in chimeric animal. This chimeric animal is interbred with normal animal of the same strain to produce offspring among which some will be homozygous for this gene knockout thereby completely lacking the concerned gene. However, the productivity of homologous recombination accounts just up to  $10^{-2}$  to  $10^{-3}$  mix of DNA (Gaj et al. 2013). In diploid organisms, which contain two alleles for most genes, and may as well contain several related genes that collaborate in the same role, additional rounds of transformation and selection are performed until every targeted gene is knocked out. Selective breeding may be required to produce homozygous knockout animals.

### Site-Specific Nucleases as Tools for Gene Knockout

Apart from homologous recombination between native gene and insert vector, genome editing can also be rather rapidly achieved by the use of highly specific and precisely programmable nucleases (enzymes that cut DNA), which produce sequence changes in regions of our interest by creating double-strand breaks (DSBs). These DSBs are later repaired by various cellular mechanisms naturally present in the cells. However these repair mechanisms including non-homologous end joining (NHEJ) is highly prone to error. Thus these repairs would cause several gene insertions, deletions, or substitutions in the target area (Cox et al. 2015; Gaj et al. 2013; Sander and Joung 2014). These insertion/deletion-based mutations may interrupt or eliminate or render the gene inoperational thus creating

gene knockout. These “programmable” nucleases include mainly meganucleases, transcription activator-like effector nucleases, zinc finger nucleases, as well as CRISPR/Cas9 system (Epinat et al. 2003; Jinek et al. 2012; Miller et al. 2011; Urmov et al. 2010). Among these, the last three systems, zinc fingers, TALENs, and CRISPR are currently exploited for the purpose of gene knockout research.

#### Zinc Finger Nucleases

Zinc finger nucleases (ZFNs) are restriction enzymes broadly utilized in genome building for starting double-strand breaks. They are referred to go about as site explicit endonuclease which can tie to DNA at a particular site (Gaj et al. 2013). Zinc finger nucleases (ZFNs) contain two sections, a zinc finger DNA restricting area and a DNA cleavage part. The DNA holding area is comprised of 3–6 zinc finger rehashes which can additionally perceive and tie 9–18 base combines in a particular DNA grouping (Gaj et al. 2013). On the other hand, the cleavage domain includes a type II restriction endonuclease FokI. At the point when both the domains are assembled together, the zinc finger endonuclease protein goes about as a profoundly compelling genomic scissors. When conveyed in a cell, zinc finger nucleases (ZFNs) deliver site explicit DNA double-strand break followed by homologous recombination. As ZFN plasmids can communicate ZFN and successfully focus on a double-strand break, they give a great chance to predesign a set up to insert or delete a specific area in the genome. ZFNs give a few advantages in focusing on genome altering such as:

- The ZFNs can easily incorporate or interrupt any genome location.
- Mutations produced by ZFNs are permanent and can be hereditary.
- Genome editing is possible using a single transfection round.
- They can be used for a wide range of mammalian cell lines, and positive clone selection requires no antibiotic selection.
- Knockout/knockin results are seen to occur almost within 2 months. Additionally, zinc

finger nucleases (ZFNs) are used in many cell lines to produce full knockout.

- In cell-based screening methods, they can be used to produce knockin cell lines where endogenous target genes can be tagged with promoter, reporter, or fusion tag proteins.
- They are also useful for generating higher amounts of specific proteins or antibodies in cell lines.
- Another important aspect of the ZFN technology is that it does not need selectable markers to identify the targeted events or cells. This has a huge practical importance especially in industrial applications where recombinant protein is manufactured, and continuous expression of exogenous and undesirable marker genes is undesirable.

Although zinc finger nucleases (ZFNs) show several promising effects, there are also chance of having potential side effects. When the ZFN constructs do not target specifically and remain off target, cleavage takes place at random creating many DSBs in the genome beyond the ability of repair mechanisms causing cellular apoptosis. Off-target cleavage also generates random integration in the host genome increasing the risk of immunological response developed by cells in response to therapeutic agents.

#### TALENs (Transcription Activator-Like Effector Nucleases)

TALENs are enzymes which are genetically engineered to edit several genes. These enzymes are basically isolated from the bacteria of *Xanthomonas* species, and in the bacteria, they participate in binding and activating the host promoter. Similar to ZFNs, TALENs also contain two groups fusing transcription activator-like (TAL) proteins with FokI nuclease (Joung and Sander 2013). TAL protein consisting of repeating motifs composed of 33–34 amino acids which can strongly recognize nucleotides of interest (Gaj et al. 2013). They are also known as repeat variable di-residue (RVD) due to their variable nature. As in TALENs, there exists a direct relation within DNA and amino acid recognition; it is possible to engineer a specific domain to bind DNA by

changing the combination of repeating motif with specific RVD. By fusing TAL with FokI, it can effectively cut the genome. In the presence of two domains of TALENs, FokI create a double-strand break. After constructing TALENs, they are transfected to host cell with the help of plasmid vector. Inside the host cell, the construct gets expressed and has access to the genome by entering into the nucleus. Additionally, in cells, TALENs could also be transferred as mRNA which does not require genomic integration process. In comparison with zinc finger nucleases (ZFNs), TALENs offer several advantages, such as:

- The design of TALEN is much easy in comparison with ZFNs. Many TAL repeats can be created with RVD code which will bind strongly with the genomic DNA with high affinity.
- The amount of TALEN repeats can be extended based on the desired length.
- TALENs are used widely for plant genome modification.
- They are useful for the production of biofuels.
- They have been used to generate knockout in organisms such as zebrafish, rat, mice, or *C.elegans*.

#### CRISPR/Cas9 (Clustered Regularly Interspaced Short Palindromic Repeats Associated Nuclease Cas9)

Genome editing technology re-emerged in 2012 with the development of CRISPR/Cas9 system, which is an important genetic manipulation tool derived from the defense systems of several bacteria offering protection against viruses and plasmids. This method is easy to apply and has been used in diverse experimental animal models apart from cell lines, plants, and even in human clinical trials.

CRISPR/Cas9 is a rapid genome editing method which is used to delete or modify specific sequences of DNA which contains a guide RNA complexed with a Cas9 protein (Gaj et al. 2013). CRISPR can be found naturally in certain types of bacteria. When invaded by a bacteriophage, the bacteria use CRISPR/Cas9 method to cut and disintegrate the viral DNA. The guide RNA

(gRNA) can be engineered to match a desired DNA sequence (gene of interest to be knocked out) through simple complementary base pairing, as opposed to the time-consuming assembly of constructs required by zinc fingers or TALENs (Ni et al. 2014). In bacteria, there exist three types of CRISPR-associated systems; among them, type II endonucleases are most widely studied for genome editing associated with Cas9 endonuclease of *Streptococcus pyogenes*. At this method, once cut into small parts, the invading DNA gets incorporated into CRISPR locus. Once transcribed in the cell, small short repeats of RNA or crRNA/CRISPR RNAs are generated within the cell. crRNA next gets joined by another non-coding RNA known as trans-activating CRISPR RNA or tracrRNA and activates the endonuclease Cas9 to target the invading viral DNA. crRNA together with tracrRNA forms a single guide RNA or sgRNA. CRISPR/Cas9 generates DNA double-strand breaks which can be repaired by two mechanism: (i) non-homologous end joining or NHEJ, where homologous double strands are absent and (ii) homology-directed repair which occurs in the presence of synthetic DNA repair template. Following the discovery of CRISPR/Cas9 system, it has been extensively used in several organisms for gene targeting such as plants, humans, *C.elegans*, zebra fish, yeast, drosophila, or mouse. They are now days used to produce single-point mutations in the presence of single gRNA. In comparison with TALENs and ZNFs, CRISPR/Cas9 is easy to use as here only crRNA required redesigning to target any gene specifically. Additionally, this method also enables genome-wide analysis of gene function by producing libraries of large gRNA.

#### Applications of Gene Knockout Technology

Using engineered or bacteria-derived nucleases, the advancements in genome editing technologies have provided diverse possibilities of targeting and manipulating genomic sequences of almost all eukaryotic as well as prokaryotic systems. Gene targeting or knockout has incredibly

extended our ability to investigate the contribution of genetics to various diseases by employing the creation of more accurate animal and cell-based models of pathological processes. KO technologies have displayed extraordinary potential in a variety of fields including human diseases, pharmacy, drug designing, basic research, and applied biotechnology as well as in biomedical research benefiting mankind tremendously (Li et al. 2020). Below are the major applications of gene knockout and associated genetic engineering technologies in diverse fields.

## Gene Editing and Human Health

Targeted gene modification via chimeric genome editing tools is a powerful method to assess gene function and precisely manipulate cellular behavior and function (Li et al. 2020). Gene KO technology has made it easier to understand the etiology behind various diseases and to clarify molecular mechanisms. It has extended to a border field of cancer research, for example, engineering of hematopoietic stem cells (HSCs) and tumor-targeted T cells. Genome editing tools like zinc finger nucleases (ZFNs), TALENs, and CRISPR/Cas9 have revolutionized the domain of cancer research (Sánchez-Rivera and Jacks 2015). Similarly, studies have shown that the use of HER2-positive cell-penetrating peptide (CPP) conjugated to mammalian mTOR-specific ZFN made the mTOR locus nonfunctional and inhibited relevant cancer signaling pathways (Li et al. 2020), providing insight into the design of novel molecular-targeted therapeutics for breast cancer (in particular) and other types of cancers in general. Recently, TALEN gene editing technology has been used to knockout genes in cancer cells (including cells from prostate cancer, breast cancer, and hepatocellular carcinoma (HCC)) and is a very powerful and broadly applicable platform to explore gene mutations at the molecular level (Ho et al. 2018). The CRISPR/Cas9 system has attracted considerable attention, and scientists gradually consider it to be a powerful therapeutic tool for treating diseases associated with genome mutations (Ramanan et al. 2015). The ultimate

goal of cancer therapy with CRISPR/Cas9 is to remove malignant mutations and replace them with normal DNA sequences. The CRISPR/Cas9 platform also provides a new tool to manipulate noncoding regions of the cancer genome, accelerating the functional exploration of aspects that are hitherto poorly characterized (Sánchez-Rivera and Jacks 2015).

The first report in the world describing the treatment of genetic diseases through in vivo gene editing was provided by Benioff Children's Hospital at the University of California, San Francisco. There, an American man with Hunter's syndrome, was treated with the delivery of ZFNs via an AAV for in vivo genetic editing to treat his disease (Li et al. 2020). Such reports further demonstrate that gene editing has extremely important clinical applications and huge potential for the treatment of genetic diseases. Genome editing technology has also been combined with tumor immunotherapy to provide more updated options for human disease treatment. As one of the most innovative and successful approaches in tumor immunotherapy, CAR T-cell therapy was officially approved for use in the clinic in 2017 as a "breakthrough therapy" and approved its treatment for leukemia and lymphoma (Chavez et al. 2019).

CRISPR/CAS9 is showing tremendous potential in its applications with regard to the field of allograft bioengineering, including the refinement of heart transplant (Ho et al. 2018). Knocking out specific genes as cardiovascular disease prevention (CVD) approaches has also received widespread attention especially in diseases like cancer, neurodegeneration, and diabetes (Chai et al. 2018; Fan et al. 2018). Gene editing technology has applications in treatment of metabolic diseases where different knockout models have been generated to study their impact in the pathology (O'Rahilly 2009). As an important "experimental tool," the animal models of diabetes disease can be used for pathological observation, preclinical experiments, and drug screening. This technology finds its applications in neurodegenerative diseases, viral diseases, hereditary eye diseases, and hematological diseases where loss of function (gene knockout) studies are carried out to study the

onset and pathological outcomes of the defected gene. Moreover, the important and most recently observed application of gene knockout and CRISPR/Cas9-based technologies have been seen in transplantation immunology where xenografts from pigs or other animals are used to replace organs in humans by knocking out genes from human cells which play an active role in xenograft rejection (Cowan et al. 2019). Ultimately, researchers aim to use gene knockout technologies like CRISPR/Cas9 to rapidly develop genetically modified pigs which will be rightly poised to provide compatible xenografts to human patients.

### Use of Gene Knockout in Biomedical Research

Apart from its potential use in treating human diseases and improving human health, gene editing technologies have a vital role to play in biomedical research including development of refined cell imaging techniques, studying the epigenetic modification as well as regulation of gene expression under various pathophysiological conditions, and therapeutic drug designing as well as genetic diagnosis of hereditary diseases in advance of symptoms (Hongbao et al. 2013, Li et al. 2020). Although the off-target effect in the implementation of gene editing technology still needs further optimization, innovative genome editing complexes and more specific nanostructured vehicles have improved efficiency and reduced toxicity during the delivery process, bringing genome editing technology closer to the clinic. With deeper exploration into this technology and the cooperation of the world scientific community, it is reasonable to believe that genome editing technology has the potential to ultimately elucidate biological mechanisms behind several dreadful diseases as well as their treatment, thus providing novel therapies and finally promoting the development of the life sciences.

In summary, knockout animal models such as knockout mice are exceptional tools to study the function and regulation of certain important genes in biomedical research investigations. Despite several ethical and moral concerns and limitations in applying this technology, gene knockout techniques provide useful insights into understanding

the progression of several diseases. The creation of a gene knockout mouse is a watershed landmark and a massive advance in the pharmaceutical as well as biomedical fields. Such genome editing methods will allow scientists with ample opportunities and powerful tools for investigating gene function during disease and development. With more advancement in genetic engineering and molecular biotechnology, future gene knockout technology will revolutionize the field of medicine and disease management.

## Knuckle-Walking

Roshna E. Wunderlich

James Madison University, Harrisonburg, VA, USA

## Definition

Knuckle-walking is a form of quadrupedal locomotion in which forelimb weight is born on the dorsa of the middle phalanges of the hand (not actually on the “knuckles” as its name implies). The hand is held in a position in which the interphalangeal joints are flexed and the metacarpophalangeal joints are extended or in a neutral position (Fig. 1). This is in contrast to the palmigrade or digitigrade hand positions used by most mammals in which the palmar surfaces of the hand and/or digits, respectively, make contact with the substrate.

## Distribution

Knuckle-walking is primarily performed by the African great apes, *Pan troglodytes* (chimpanzees), *Pan paniscus* (bonobos), *Gorilla gorilla* (western gorillas), and *Gorilla beringei*

**Knuckle-Walking, Fig. 1** Image of a gorilla using knuckle-walking. Note the weight is borne on the middle phalanges, the wrist is in a neutral position, the elbow is extended, and the shoulder is internally rotated. (Photo credit: Dr. Angel Zeininger)

(eastern gorillas); however, it has also been documented in the giant anteater (*Myrmecophaga tridactyla*) in the order Xenarthra. In general, knuckle-walking is adopted during terrestrial, and frequently arboreal, quadrupedal locomotion by large-bodied arboreal animals possessing long, curved digits. Knuckle-walking allows these animals to retain these long, curved digits, useful for arboreal locomotion such as climbing and suspension while protecting them from increased bending loads during the compressive loading of terrestrial quadrupedalism. The evolution of knuckle-walking in the African apes has received considerable attention because of the implications of a common versus independent ancestry for models of the evolution of human locomotion (see below).

## Mechanics and Functional Variation

The manner and extent to which animals knuckle-walk vary among its practitioners, although all knuckle-walkers bear weight on their middle phalanges and tend to use wrist postures in which extension is limited. All adult African apes knuckle-walk consistently when walking quadrupedally on the ground; however, considerable interspecific and intraspecific variation has been observed in the extent to which *Pan* uses knuckle-walking in the trees. While *P. paniscus*

tends to be more arboreal in general, traveling using arboreal pathways (Doran 1993; Doran and Hunt 1994), *P. paniscus* as well as *P. troglodytes schweinfurthii* (eastern chimpanzees) at Mahale, Tanzania, tend to use palmigrade quadrupedalism in the trees (83–87% for *P. paniscus* and 77–94% for *P. troglodytes schweinfurthii*), while *P. troglodytes verus* (western chimpanzees) in the Tai National Park, Ivory Coast, tend to use knuckle-walking quadrupedalism in the trees most (57–72%) of the time (Doran and Hunt 1994).

Variation in the manner in which African apes knuckle-walk has been used in support of hypotheses of parallel ancestries for *Pan* and *Gorilla* knuckle-walking. Variation has been documented in forelimb position, hand position, force distribution across the digits, and the extent to which members of each species use knuckle-walking during ontogeny (growth). Gorillas tend to use more pronated forelimb positions than chimpanzees, and gorillas tend to use more neutral distal forelimb positions in which the hand and wrist are stacked on top of one another compared to more extended positions in chimpanzees (Tuttle 1969; Inouye 1992, 1994; Kivell and Schmitt 2009). Gorillas and bonobos use hand positions in which the palm faces backward (posteriorly), while chimpanzees use a combination of palm-in and palm-back positions (Wunderlich and Jungers 2009; Matarazzo 2013). Plantar pressure distribution has been used to measure the manner in which force is distributed across the hand during knuckle-walking. During terrestrial knuckle-walking, gorillas tend to distribute pressure evenly across digits 2–5 and consistently touch off and have the highest pressure on the second digit (the index finger in humans). During arboreal knuckle-walking, bonobos also distribute force across digits 2–5, but they touch down and off on digit 3 (Samuel et al. 2018). Chimpanzee pressure distribution is more variable than gorillas or bonobos on both terrestrial and arboreal substrates, likely because of their variation in hand posture. The highest pressure and touch off can be on digits 2, 3, or 4, and this is dependent on their hand posture (Wunderlich and Jungers

2009; Matarazzo 2013). Matarazzo (2013) found the third digit experienced the highest load and was the last to be loaded in chimpanzees in terrestrial palm-back positions and attributed this to the longer third digit in chimpanzees compared to gorillas. However, all of these pressure studies have been, by necessity, conducted only in captive settings and on a limited number of individuals. African apes in the wild must knuckle-walk on a variety of terrestrial and arboreal substrates and thus likely show much more variation in their hand postures (knuckle-walking and otherwise) and digit loading than captive studies can quantify. Indeed, a study of wild mountain gorillas' (*Gorilla beringei beringei*) terrestrial hand postures showed that only 60% of the individuals used exclusively knuckle-walking on the ground, while others sometimes loaded the dorsa of their proximal phalanges (fist-walking) or metacarpals (Thompson et al. 2018).

Use of knuckle-walking varies during development in African apes. While both gorillas and chimpanzees (*P. troglodytes*) begin palmigrade quadrupedalism at 4.5–5.5 months, gorillas begin using knuckle-walking postures much earlier than chimpanzees. By 10–15 months gorillas use knuckle-walking 61% of the time, and by 2 years 97% of their quadrupedalism is knuckle-walking. Chimpanzees engage in very little quadrupedalism at young ages (6–23 months), and when they do, it is predominantly (72%) palmigrade. It is not until 29 months that knuckle-walking comprises over 50% of their quadrupedal bouts. When body size is considered (e.g., a 2-year-old chimpanzee compared with 10–11-month-old gorilla), locomotor patterns are more similar between chimpanzees and gorillas (Doran 1997).

## Morphological Correlates

Because of the implications for human evolution (see below), extensive attention has been given to morphological features associated with knuckle-walking, their variation among knuckle-walking apes, and their presence in the fossil record.

Although not useful for examining the fossil record, all extant knuckle-walking apes exhibit skin callous, dermatoglyphs, and depilation on the dorsum of the middle phalanges. Most features discussed with respect to knuckle-walking adaptations of the upper limb are musculoskeletal features. African apes have more robust phalanges than the Asian apes who are more highly arboreal and do not knuckle-walk (orangutans use a hand position called “fist-walking” that seems to serve the same purpose of protecting their long, curved fingers). Knuckle-walking has also been associated with a unique yet controversial suite of musculoskeletal features of the wrist. These include the fusion of two wrist bones, the scaphoid and os centrale (also present in humans), a dorsal ridge on the capitate and hamate, a deep groove and dorsal ridges on the metacarpal heads, wide articular surfaces on metacarpal heads 3 and 4, and a distally extended and medially projecting dorsal ridge on the distal radius. Most of these features are believed to be functionally associated with prevention of excessive extension of the wrist and hand.

Considerable variation has also been noted in these and other morphological features associated with knuckle-walking. Like the functional variation, morphological variation and ontogenetic variation have been cited as evidence for independent evolution of knuckle-walking in African apes. Gorillas have shorter and less variable ray lengths than chimpanzees (Inouye 1992). Gorillas have relatively longer and more robust fifth metacarpals, while chimpanzees have third digits substantially longer than the other digits such that they are positioned anterior to the other digits during knuckle-walking (Matarazzo 2013). While *Pan* consistently exhibits capitate waisting, extension-limiting ridges and concavities on the hamate and capitate, and a dorsal concavity and ridge on the scaphoid, these features are less pronounced and present with considerably less frequency in *Gorilla* (Kivell and Schmitt 2009). Similarly, while *Gorilla* engages in more frequent knuckle-walking at much earlier ages than *Pan* (Doran 1997), many of these “knuckle-walking” features of the wrist do not develop earlier as would be expected if these morphologies are

either necessary for or a result of knuckle-walking behaviors (Kivell and Schmitt 2009). Furthermore, dorsal ridges on the wrist bones and metacarpal heads are argued to be the result of cartilage remodeling during ontogeny rather than osteological features that limit extension within the wrist and hand during knuckle-walking (Simpson et al. 2018).

## Implications for Human Evolution

Acceptance of the molecular evidence that *Pan* and *Homo* share a more recent common ancestor than either does with *Gorilla* brought knuckle-walking and its associated morphological features to the forefront of a debate regarding the nature of locomotion in the last common ancestor (LCA) of *Pan* and humans. While morphologically based phylogenies allowed for the evolution of knuckle-walking in a *Gorilla*-*Pan* clade, the monophyly of *Pan*-*Homo* requires that either the LCA of *Gorilla*, *Pan*, or *Homo* was a knuckle-walking quadruped (a scenario usually considered to be combined with a partially arboreal lifestyle as in modern African apes) or knuckle-walking has evolved more than once in parallel within the Hominae (the group including *Gorilla*, *Pan*, *Homo*; Fig. 2).

In light of the molecular evidence supporting a close relationship between African apes and humans, Washburn (1967) first explicitly suggested that human evolution included a knuckle-walking stage prior to bipedalism. Since then, various researchers (e.g., Corruccini 1978; Shea and Inouye 1993; Begun 1993, 1994; Richmond and Strait 2000; Richmond et al. 2001) have supported a knuckle-walking ancestor based on (1) suggested homology of knuckle-walking features in African apes, meaning these features would have to have evolved before the *Gorilla*-*Pan*/*Homo* split, and (2) evidence in early hominins and/or modern humans of morphological features associated with knuckle-walking such as the distal projection of the dorsal radius, fused scaphoid-os centrale, waisted capitate neck, and long middle phalanges (see Richmond et al. (2001), Table 3, for complete list and explanation).

Support for parallel evolution of knuckle-walking in *Pan* and *Gorilla* (and usually a more arboreal common ancestor of *Pan* and humans) has been based on demonstrations of (1) morphological variation across African apes in most of the features traditionally associated with knuckle-walking (detailed in Kivell and Schmitt 2009); (2) variation in the ontogenetic trajectory of knuckle-walking morphological features

**Knuckle-Walking, Fig. 2** Alternative scenarios for the evolution of knuckle-walking. Knuckle-walking as a behavioral trait or suite of morphological features is indicated by the solid rectangle, and bipedalism is indicated by the hashed rectangle. (a) Knuckle-walking evolves independently in *Pan* and *Gorilla*, and terrestrial bipedalism

evolves in humans. This scenario implies an arboreal last common ancestor of African ape and humans. (b) Knuckle-walking is homologous in *Pan* and *Gorilla* and present in the last common ancestor. Knuckle-walking is retained in *Pan* and *Gorilla* and is lost upon the acquisition of bipedalism in the hominin lineage

(Dainton and Macho 1999; Kivell and Schmitt 2009) suggesting the same adult morphology may not reflect the same developmental pathway; (3) functional variation in knuckle-walking across African apes (e.g., Tuttle 1967; Inouye 1992, 1994; Shea and Inouye 1993; Matarazzo 2013) that suggests knuckle-walking itself is a different phenomenon in different animals; (4) functional or biomechanical similarities between climbing and bipedalism (e.g., Prost 1980; Fleagle et al. 1981; Stern and Susman 1981; Ishida et al. 1985); (5) use of bipedalism by great apes frequently in the trees (e.g., Hunt 1994; Thorpe et al. 2007; Crompton et al. 2010); and (6) the retention of arboreal features in early hominins (e.g., Tuttle 1981; Jungers, 1982; Stern and Susman 1983; Duncan et al. 1994) that implies bipedalism evolved in an animal adapted primarily for an arboreal environment and that used bipedalism when it came to the ground.

Reconstruction of the morphology and behavior of the last common ancestors of *Pan* and humans is fundamental to our understanding of the selective pressures and mechanisms by which our hominin ancestors diverged from other apes, and clarifying the evolution of knuckle-walking, a mode of locomotion shared almost uniquely within the animal kingdom by *Pan* and *Gorilla*, is essential to this process. Disentangling the morphological correlates of knuckle-walking, furthering our understanding of the ontogeny and biomechanics of knuckle-walking, and improving the representation of apes and the earliest hominins in the fossil record will all be critical to resolving debates regarding the morphology and behavior of African apes and our ancestors.

## Definitions

Action Pattern,  
Fixed (FAP)

Synonymous to  
“Erbkoordination.”  
“Innate” behaviors similar to reflexes, the basic, species-specific elements of behavior, generated by neuronal “pattern generators” in the motor column of the spinal cord and being disinhibited either via short sensory-motor reflex loops or via the long associative loops activating the pallial motor neurons. The evolutionary prefabricated responses for the standard challenges of life. Their intensity varies with the quality of an external stimulus (see sign stimulus) and with motivation.

Behaviorism

Late nineteenth and twentieth century proponents were Edward Thorndike, John B. Watson, Burrhus F. Skinner. Although at least partially acknowledging the role of inheritance (e.g., reflexes), behaviorists held that behavior was mainly learned. Skinner denied heritable, species-specific

|                           |                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                       |                    |                                                                                                                                                                                                                                                                                                                                                                                                        |

| Evolutionary Epistemology | elements of behavior and “private” factors, such as emotions.<br>EE is a naturalistic approach, emphasizing the importance of natural selection in two primary roles: (1) In selection as the generator of our senses and cognitive mechanisms, explaining the “fit” between them and the world; (2) Trial and error learning and the evolution of scientific theories are construed as selection processes (Stanford Encyclopedia of Philosophy <a href="https://plato.stanford.edu/entries/epistemology-evolutionary/">https://plato.stanford.edu/entries/epistemology-evolutionary/</a> ). Main proponents were Donald T. Campbell, Karl Popper, Rupert Riedl, and Gerhard Vollmer. KL contributed significantly to EE (1941a, 1973b, 1977, 1992). | Innate Schoolmarm  | KL’s main argument against the stance of behaviorists (above), that most, if not all behavior would be learned (1978, 1980): To be adaptive, learning needs a (species-specific) innate template to direct individual attention towards the relevant contexts, thereby filtering the wealth of contexts and stimuli an individual may be exposed to.                                                   |
|                           |                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                       | Ethological Theory | On the mechanistic and also, functional causation of behavior (Tinbergen 1963), essentially a theory of instincts (Tinbergen 1951; Lorenz 1978). Behavior is adapted and behaviors (action patterns) are innate elements, triggered by external (key) stimuli and internal motivation. Learning makes for flexibility; what will and can be learned is constrained by an “innate schoolmarm” (above).  |
| Imprinting (Social)       | How altricial birds such as Greylag geese quickly learn who their parents are; time pattern different in precocial birds. Unclear whether this also applies to mammalian pups. In coherence with other elements of the Lorenz-Tinbergian theory, an “innate schoolmarm” provides a template in naïve hatchlings/pups in which fitting “sign stimuli” (shape, movement, sound) trigger a quick, lasting learning process. Further investigated by E. Hess.                                                                                                                                                                                                                                                                                             | Kindchenschema     | Earned KL and Niko Tinbergen the Nobel Prize in medicine 1973, together with Karl von Frisch.<br>Example of a syndrome of “sign stimuli” (“Schlüsselreize,” below), facilitating caregiving motivation on side of the receiver. This syndrome includes stimuli such as big, roundish heads, large eyes, short ears, and noses. Met in toddlers, in mammalian puppies or in precocious bird hatchlings. |

|                                                |                                                                                                                                                                                                                                                                                                                                                                                                                                                                           |               |                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                               |
|------------------------------------------------|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|---------------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Psychohydraulic Model of Motivation            | Cybernetic model of thought, holding that the specific motivation for each action pattern would accumulate (the “action specific potentiality”) and finally “spill over” if not acted out. Hence, the intensity of a behavioral response would be caused by the strength of an external triggering stimulus in combination with the intrinsic motivation. Today considered outdated as a general theory of motivation.                                                    | Sign Stimulus | all three modalities are active at the same time. “Schlüsselreiz-Konzept”: Perception coevolved with relevant stimuli in a way, that they specifically fit each other like lock and key, for example, red belly of opponent triggering territorial aggression in sticklebacks (Tinbergen 1951) or the stimulus features of the “Kindchenschema” (Lorenz 1973b, 1978).                                                                                                                                                                                                                                                         |
| Reflex Chain Theory                            | Pavlovian theory that behavior consists of chains of reflexes, as every action changes the stimulus context/propriosensory feedback and thereby, triggers the next action. Flexibility by learning, for example, conditioned reflexes. Refuted by E. v. Holst and KL, based on their results that behaviors can occur “spontaneously” and that via “appetitive behavior” individuals may actively seek for certain stimuli. Base for developing the “ethological theory.” | Vitalism      | Conceptual system leaving metaphysic loopholes in science. Proponents are early twentieth century biologists and psychologist, such as Gavin Rylands de Beer (1899–1972) and Jakob von Uexküll (1864–1944). They insist on a metaphysical (nonmaterial) element in instinct (“could neither be explained scientifically, nor would they be in need of such an explanation”). In contrast, KL always held that all behavior needs to be explained solely on the base of the “physicochemical mechanisms” in the brain. Thereby, he formulated the materialistic-reductionistic principles all science is obliged to adhere to. |
| Reizsummenregel (Alfred Seitz’s Summation Law) | Different external stimulus modalities trigger the same behavior and reinforce each other. For example, following behavior in precocious bird hatchlings towards an subject/object they are imprinted, is triggered by the shape, the movement and the vocalization of a “parental” subject/object; strongest if                                                                                                                                                          |               |                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                               |

### The Genesis of a Genius Observer: A Commented Chronology

Based on earlier biographies and contributions (e.g., Bischof 1991; Evans 1975; Festetics 1983; Föger and Taschwer 2001; Koenig 1988; Kotrschal et al. 2001; Lorenz 1985, Lorenz et al.

1998; Nisbett 1976; Schleidt 1988; [http://klha.at/kl\\_cv\\_cv.html](http://klha.at/kl_cv_cv.html)).

Konrad Zacharias Lorenz (KL) was born in Vienna/Austria and raised in Altenberg, a village at the river Danube NW of the capital Vienna, November 7, 1903. He was the last of the two children (his brother Albert was 18 years older, see A. Lorenz 1952) of Emma and Adolf Lorenz. Extremely talented and ambitious father Adolf (1854–1946) was of working class origin (Adolf's father was a saddler). He became professor for orthopedics at the Medical branch of the University of Vienna and a world leader in the innovative treatment of innate hip dysplasia and other skeletal conditions. He earned and – for different reasons – lost a fortune three times over his lifetime. For his scientific achievements, Adolf was himself nominated for the Nobel Prize eight times but never received it. In 1903, when KL was born, the representative and spacious historicistic Lorenz family villa in Altenberg was just completed. In this house and its park-like garden, KL kept and raised a wealth of different animals from early childhood on and thereby, acquired his mental library of systematic observations of animal behavior which became the substrate for developing his general basic theory of behavior and psychology, essentially a theory of instincts.

KL's mother Emma Lorenz (prev. Lecher, 1862–1936) was a Vienna Belle Époque lady, working hard in her husband Adolf's praxis. She was born as one of six children of the leftish journalist Zacharias Lecher, for some time director of the liberal Austrian newspaper *Die Presse* (still existing today). Emma was related and befriended with a range of leading Vienna entrepreneurs and artists, among them writer Richard Engländer, alias Peter Altenberg (1859–1919). Hence, KL grew up in a wealthy, cultural, and intellectual fin de siècle upper-class environment. But he also grew up embedded in nature and in intense touch with animals, his great passion and keen interest from early childhood on. KL was co-raised by his nurse Resi Führinger, a farmer's daughter, who kept being an essential assistant in animal keeping, even as the boy grew into a young man. At the same time, KL shared with his father a faible for the newest technology, notably, posh

cars and motorcycles. Within this frame the gifted child developed into a genius observer and biologist, able to express himself in perfect German, English, and French, both in speaking and writing. Like Sigmund Freud, his writings were not only cheered for contents but also for their literary quality. Hence, the quality of KL as a biologist was rivalled only by his skills as an incredibly charismatic communicator. This was certainly a blessing for the new discipline of ethology/behavioral biology to become rapidly acknowledged and popular among scientists and laypersons as well. On the downside, particularly in the second half of the twentieth century, KL's assertive style and also, his skeptical stance towards hypothesis testing were not in favor for the development of the science of behavioral biology.

KL was born into the early twentieth century, which saw a dynamic and diverse development of psychology and behavioral sciences. In 1904, the University of St. Petersburg-based Physiologist Ivan Pavlov (1849–1936) was awarded the Nobel Prize for his research on the conditioned reflex and the development of the “reflex theory” of behavior. This theory was refuted 30 years later by KL and Erich von Holst and developed into the “ethological theory,” based on the simple, but revealing experiments by von Holst, showing that motor behavior can be generated even at the absence of external stimuli or sensory feedback. At the beginning of the twentieth century Sigmund Freud (1856–1939) published some of his most well received concepts, including on “drives.” Interestingly, KL never explicitly related to, or quoted Freud, except for ridiculing some of Sigmund Freud's “drives,” for example, “Thanatos” (the death drive). Still, their instinct theories were relatively similar to each other, supporting the assumption that KL was influenced by Freud. This is more likely, as KL learned most of his basic psychology at University of Vienna-based psychologists Karl Bühler (1879–1963; “Gestalt psychology”) and Charlotte Bühler (1893–1974; “Viennese Child Psychology School”).

Niko Tinbergen, KL's lifelong colleague and lifelong close personal friend, was born April 15, 1907, in Den Haag (died 1988 in Oxford/UK), The Netherlands. At that time, 4-year-old

KL started keeping animals in aquaria, such as spotted newts, assisted by his nurse, he raised a first duckling which imprinted on him and was disappointed by the lack of loyalty of his first dog, a dachshund. The little boy first wanted to become an owl, but then changed his mind in favor of being a duck, when he learned that owls cannot swim, or a goose, motivated by Selma Lagerlof's "Niels Holgerson." KL entered elementary school in 1909 and soon engaged in first systematic studies on crustaceans.

In 1910 Oskar Heinroth, Berlin zoo-based biologist and one of the founders of the "Vergleichende Verhaltensforschung" (comparative ethology) published his classical paper on the behavior of ducks. He was later "adopted" by young KL as a scientific father figure and mentor (Koenig 1988). KL's own father Adolf was tolerant towards the animal passion of his son, turning scientific already early on; but he did not see his son's future in zoology. Instead, he would later urge KL to study medicine, which would turn out to benefit the scientific development of KL.

In 1915, KL entered the Vienna elite high school "Schottengymnasium," where he remained until 1921. During this period, post-World War I Austria degenerated into an intellectually dull catholic "Ständestaat" dictatorship, terminated 1938 by the Nazi occupation. Under the Ständestaat regime teaching evolution at schools was discouraged, which only changed with the Nazi regime. Therefore, it is remarkable that KL was inspiringly taught about Darwin and evolution in high school by Philip Heberdey, a Benedictine monk. Basically, he had already discovered evolution by himself by observing nature and reading Wilhelm Bölsche at the age of 10. During high school, KL started keeping and breeding many songbirds.

In 1918 Wallace Craig (1876–1954), University of Maine-based, US experimental psychologist and behavior scientist published "The comparative ethology of Columbidae" (pigeons), a classic of late US zoologist Charles O. Whitman (1842–1910). This influenced KL to a significant extent, as did his regular exchange of letters with Oskar Heinroth (Koenig 1988). Later, during his

time of assistantship at F. Hochstetter (below), KL was in contact with W. Craig and he, as well as O. Whitman and O. Heinroth laid the ground for classical ethology, established later by KL and N. Tinbergen. Actually, W. Craig first criticized first KL's adherence to the Sherrington/Pavlovian reflexology, on the basis of the existence of "appetitive behavior" (i.e., the active search for favorable contexts or stimuli), long before E. v. Holst (below) convinced him of the flaws of this theory. All of them may be considered the founders of ethology, which was always fully acknowledged by KL.

In 1921, KL excelled in his final high school exams. Together with his friend Bernhard Hellmann he conducted observational and experimental work on crustacean development and also, on aggression in a *Geophagus* cichlid. This crucial experience inspired KL's concept on drives and motivation, which is generally referred to as the KL "psychohydraulic model of motivation" and was a base for his most widely perceived and controversial book *On aggression* (1963, 1966). His Jewish companion and friend Bernhard Hellman would later be killed in a Dutch Nazi concentration camp.

In 1922, his father Adolf urged KL to study medicine instead of Biology or Paleontology, as preferred by KL; he sent his son off to take two semesters of medicine courses at the New York Columbia University. The main intention behind this was to interrupt KL's relationship with his long-term girlfriend Margarethe "Gretl" Gebhardt (1900–1986), his later wife. Gretl was KL's close partner and companion from early childhood on but was lower class in origin and therefore, not considered an adequate match. However, the paternal attempt to influence KL's mate choice failed. They finally married (below), Gretl became an engaged medical doctor and contributed much of the income of the growing young family before till and after World War II. In the USA, KL spent more time studying marine organisms on his own in the field than with his official university duties. He also met the eminent, California Institute of Technology-based US biologist and geneticist Thomas Hunt Morgan (1866–1945, Nobel Prize

1933), but it remains unclear how influential this was for KL's further development.

KL successfully engaged in motorcycle racing from 1924 to 1930, when he broke his lower jaws in an accident and ever since wore his characteristic chin beard. On intervention of Gretl, he had to stop racing. Still, Gretl herself was an enthusiastic and successful motorcycle racer. She only stopped racing after she had two children.

In 1926 KL hand raised his first jackdaw "Tschok," an experience which contributed much to his theory on imprinting. From 1927 till the mid of the 1930s he published a series of papers (e.g., 1927, 1933), initially mentored by eminent Berlin ornithologist Erwin Stresemann (1889–1972). These papers on innate behavior and instinct laid the ground for his early international reputation as a leading behavioral biologist, particularly with birds.

KL and Margarethe Gebhardt, both students of medicine, married on June 24, 1927. Their first son Thomas was born on October 31, 1928 (–1982). He became an acknowledged researcher in physics at the University of Munich. KL finished his medical PhD and thereupon, accepted an assistant professorship at the University of Vienna II. Anatomical Institute, headed by eminent comparative anatomist and embryologist Ferdinand Hochstetter (1861–1954). KL learned much about ontogenetic development, which influenced his thinking quite a bit. In parallel, KL started studying zoology, mainly at the University of Vienna Zoological Institute of Jan Versluys. He accidentally cross-bred his male German shepherd with his wife's female Chow Chow, resulting in a behaviorally most fascinating dog ("Stasi"). Stasi also became the star in one of KLs most popular books (*Man Meets Dog*; 1950, 1954). Inspired by this book, a new FCI dog breed was established in the 1960s, the "Eurasier." In 1930 their daughter Agnes (married "von Cranach" – 2009) was born.

In 1931 KL met Oskar Heinroth for the first time, followed by 10 years of intense correspondence between the two, mainly on bird behavior. These letters were edited (i.e., cleansed of political and private content) and published 1988 by Otto Koenig (1914–1992), a Vienna-based

naturalist and ethologist and scholar of KL, who established the Vienna "Biologische Station Wilheminingenberg," which still exists as "Konrad Lorenz Institute of Comparative Ethology," presently part of the Veterinary University of Vienna.

In 1932, KL saw "fly catching" behavior at the absence of an aerial insect in a captive starling. He concluded, that behavior can be "spontaneous" (i.e., triggered by intrinsic factors). The same year, the German Ornithological Society convened her annual meeting in Vienna. Participants, among them the King of Bulgaria, visited the "Ornithologische Versuchsanstalt," KL's private research institute, in Altenberg. Father Adolf was amused about all this fuzz about birds, but at the same time he was deeply impressed by the international and high-level attention his son received. Gretl Lorenz finished her PhD in medicine. In 1933, KL finished his zoological PhD on the topic of bird flight (see also Lorenz 1935) and met Julian Huxley (1887–1975) in 1934, at an ornithological Conference in Oxford.

When Ferdinand Hochstetter retired from his professorship in 1935, KL was longer employed by his successor at the anatomical institute, Eduard Pernkopf. KL frequently attended the seminars of the University of Vienna psychologist Karl Bühler and his assistant Egon Brunswick, who pointed KLs attention to the fact that his comparative results contradicted the vitalistic or "instinctivistic" school of W. MacDougall and the behavioristic school of J.B. Watson et al. KL was struck by the ignorance of behavioral mechanisms by these eminent experimental psychologists, as expressed in one of his letters to O. Heinroth (Koenig 1988). He felt overwhelmed by, and took responsibility for, the huge mission ahead: to produce a unified, evolutionary theory of animal and human behavior and psychology.

In 1936, KL hand raised his first Greylag goose (*Anser anser*) "Martina." This started a lifelong scientific and emotional passion, later continued at his Max Planck Institutes at Buldern and Seewiesen, and after his retirement, at the Konrad Lorenz Forschungsstelle in Grünau (below). KL met Niko Tinbergen (1907–1988; Dutch behavioral biologist, later University of Oxford-based founder of ecoethology), for the first time at a

symposium at Leiden University. A lifelong close collaboration and tight personal friendship began, manifest in hundreds of long letters (unpublished) exchanged between the two over the decades, till NT died. Their friendship outlasted all serious topical and political challenges. Ivan Pavlov died in Leningrad. The same year KL met Erich von Holst (1908–1962), in Berlin February 12, on the occasion of a lecture KL gave in Berlin. This started a lifelong cooperation. Von Holst was a German neuro-ethologist and later, codirector with KL, of the Max Planck Institute of Behavioral Physiology in Buldern and in Bavarian Seewiesen thereafter. Von Holst quickly changed the mind of KL regarding the Pavlovian “reflex chain theory” KL had adhered to till then, albeit with little enthusiasm. Both men independently reached the conclusion that “spontaneous” behavior is not just triggered by external sensory stimuli or sensory feedback. Thereby, they falsified the Pavlovian theory. This was key in establishing the new ethological theory.

In early summer 1937 Niko Tinbergen and KL cooperatively conducted experiments on the “Instinkt- Dressur-Verschränkung” (i.e., the interdigitation of instinct and learning) and investigated some of the features of innate behaviors (i.e., “Instinct and Taxis” in these behaviors, later called “Fixed Action Patterns,” one of the core concepts of classical ethology) in the garden of the Altenberg Lorenz villa. Their example was the egg-retrieval behavior (“Eirollbewegung”) in Greylag geese (Lorenz and Tinbergen 1938). The geese they worked with were F1 hybrids between greylag and domestic geese. KL recognized somewhat changed instinctive behavior in these hybrids as compared to greylags. This sparked his lifelong concern regarding the genetically caused “degeneration of instincts” in domesticated animals or in “self-domesticated” man (1974). Together with Otto Koehler (1889–1974), German ethologist, KL became editor of the “Zeitschrift für Tierpsychologie” (from 1985 continued as “Ethology”). First translations of KL papers were published in the USA, he wrote major contributions on instinct (Lorenz 1937) and became “Privatdozent” (“Habilitation,” an

academic procedure following the PhD till today in the German-speaking countries) at the University of Vienna with the *Venia legendi* for anatomy and animal psychology, because behavioral biology as a discipline was not yet established.

The Nazis occupied Austria in 1938. KL at first sympathized with the regime and even applied for NSDAP membership that year (Föger and Taschwer 2001). KL was taken by the modernistic, progress- and science-oriented appearance of the new regime, which swept out the dull catholic Austrian dictatorship. Like his father and many other biologists, he was in favor of the Nazi’s emphasis on eugenics and produced contributions in outright Nazi jargon (1940). But all evidence indicates that KL was neither racist nor anti-Semitic. Almost certainly, KL hoped that his adaptive conformism with the Nazi regime would earn him a Kaiser-Wilhelm Research Institute (the forerunner of German Max Planck Institutes) in Altenberg. However, this did not work out; KL was sent to the Russian front as an ordinary soldier in 1944, underlining his minor role in the Nazi system.

In 1938, Karl Bühler had to give up his professorship at the University of Vienna, because he rejected to divorce his Jewish wife Charlotte. The Böhlers fled to the UK and Norway and finally, to the USA. Mentored by Erich von Holst and Eduard Baumgarten, German philosopher and sociologist (1898–1982), KL became full professor for Psychology at the University of Königsberg in 1939, as one of the successors of Immanuel Kant. KL described the “Kindchenschema” (schema of childlike characteristics) and his PhD student Alfred Seitz worked out the “Reizsummenregel.”

Daughter Dagmar was born in Vienna, January 11, 1941, and the family moved to Königsberg in June. On October 10, KL was drafted into the German army. A major publication of KL on Kant’s theory of the *a priori* in the view of Darwinian biology appeared and another one on the taxonomic value of innate behaviors in anate birds (ducks, swans, and geese). From 1942 KL worked as an army psychiatrist in a military hospital in Posen/Poland, for some months, where, as

a medical doctor, he had the opportunity to get some firsthand knowledge about neurosis, particularly hysteria, and about psychosis, particularly schizophrenia. KL also assisted in the interviewing of “mixed-race” German-Polish people and in racist phenotypic measurements, which, however, left no trace in his writings. During this time he could still continue his scientific exchange, for example, with Max Planck. He once more refuted the teleological thinking of Dutch animal psychologist Bierens de Haan (1883–1958) and of other “vitalists.”

In 1942 KL was sent to the Russian front near Vitebsk, where he was captured only months later. From 1942 to 1948, KL was POW in various camps in Russia and Armenia till 1948. For example, he first worked in a hospital at Chalturin, mainly with traumatized soldiers. As a camp doctor and psychologist, KL cared for fellow prisoners at Oritshi and later, in a number of POW camps in Armenia. In friendly contact with fellow Russian doctors he saw the parallels between Nazi ideology and Marxist indoctrination, which immunized him against ideological appropriation for the rest of his life. He wrote a manuscript on general and human ethology (“The Russian manuscript”) with potassium permanganate ink on concrete sack-ing paper. At home, KL was officially declared dead. Father Adolf Lorenz died at the age of 92 in Altenberg, February 16, 1946.

On February 18, 1948, KL returned to Altenberg, together with his hand-raised Armenian starling “Friederich” in a self-knit wire cage and with the “Russian manuscript” in his backpack. This manuscript remained unpublished at first, was even lost in the 1960s, and was found in the attic of the Altenberg home of KL after his death. It was finally published by daughter Agnes von Cranach (1992).

After returning home, KL had no job. He and his family received some support by academic colleagues and friends, such as Wolfgang Schleidt, Otto Storch, Otto König, and Wilhelm Marinelli. Soon, the Austrian Academy of Sciences financed the KL research station in Altenberg with the money donated for that purpose by the English poet and writer J. B. Priestley.

KL just had money to support animal keeping. To feed the family and KL’s research team, Gretl Lorenz had given up her medical practice to run the farm of her parents near the city of Tulln. Wolfgang Schleidt (1927–), by that time associated Garden University/USA, Ilse and Heinz Prechtl (1927–2014), later professor at Groningen University, as well as Eleonore and Irenäus Eibl-Eibesfeldt (1928–), later a founder of human ethology, joined KL’s initial research team.

In autumn 1948, William H. Thorpe of Cambridge University/UK visited KL to offer him a lectureship in England. But KL was confident to receive a call from an Austrian university, which indeed happened, as Karl v. Frisch left his chair in Graz for Munich. However, Felix Hurdes, the Christian-conservative Austrian minister of education vetoed against KL, the “Darwinist.” Now, KL was ready to accept a University of Bristol lectureship position, with the additional task of ethological research at the Severn Wildfowl Trust at Slimbridge. Seemingly, Sir Peter Scott (1909–1989), British ornithologist, conservationist, painter, naval officer, broadcaster, and sportsman, was another driving force behind this.

To keep KL in Altenberg, the German Max Planck Society paid KL a moderate salary, as there were already plans to establish a Max Planck Institute for him. Hence, KL remained in a waiting position at home over 1949. His wife Gretl persuaded KL to use his talents for earning money. Hence, KL wrote two popular books, best sellers at first and long-sellers till today, one featuring autobiographic animal stories (1949, 1953: *King Solomon’s Ring*) and another one on dogs (1950, 1954: *Man Meets Dog*).

On May 5, 1950, the first ethologists meeting after the war was convened in Wilhelmshaven/Germany, reuniting KL with his friend Niko Tinbergen, who spent part of the war in a Nazi concentration camp. The Max Planck Society established the first “Max-Planck-Institut für Verhaltensphysiologie” for KL in codirectorship with E. von Holst in Buldern/Westfalia, Germany, where he moved on October 25 together with his family, joined by assistants Irenäus Eibl-Eibesfeldt, Wolfgang Schleidt, and Heinz Prechtl. KL was elected honorary member of the British

Association for the Study of Animal Behavior (ASAB).

In 1951 KL became honorary member of the German Ornithological Union as well as of the American Ornithologists Union. This started of a long series of awards, medals, honorary memberships and a total of 11 honorary degrees from universities worldwide, including Yale 1967. The University of Salzburg was the only one to withdraw KL's honorary degree in 2016, out of presentistic morality related to KL's Nazi involvement. Niko Tinbergen published his "Theory of Instincts" (1951).

In 1953, Daniel S. Lehrmann (1919–1972), US naturalist and comparative psychologist launched a vigorous critique of the ethological concept of the innate in the top-journal "Science." Discussions followed in a series of meetings, starting in Paris 1954, convened by Pierre-Paul Grassé. The conflict between nature-orientated European ethologists, notably KL and nurture-orientated US experimental psychologists, resulted in fertile discussions, prompting Niko Tinbergen (1963) to include ontogeny into his "four levels" (below). This debate dissolved the false dichotomy between "innate" and "learned" (Lorenz 1961), thereby anticipating modern epigenetics.

In 1954 the Max Planck Society decided to create a new institute for KL and Erich von Holst in Bavaria ("Seewiesen," a name coined by Wolfgang Schleidt (above), later professor for ethology at the University of Maryland. This new MPI for Behavioral Physiology was opened September 16, 1958, by Otto Hahn (1879–1968), German chemist, Nobel Prize winner 1944 and president of the Max Planck Society.

In 1960, for the first time in his life, KL SCUBA-dived coral reefs in Florida, guided by US behavioral biologist Art Myhrberg. This sparked KL's ideas on the functions of poster coloration and was a major inspiration towards his book on aggression (1963).

In 1962, Erich von Holst, his long-term colleague, friend, and mentor died.

In 1963 KL published his hotly debated and probably most influential book *Das sogenannte Böse* ("On Aggression"), where he described aggression as an adaptive system (contradicting

mainstream psychological "frustration theory"). This book triggered a wave of biopsychological research on aggression. The same year Niko Tinbergen published his programmatic paper: "On Aims and Methods of Ethology," which was dedicated to KL at the occasion of his 60th birthday. The so-called four levels of Tinbergen describe the major levels features and characters of evolutionary origin can be investigated, evolutionary and proximate function, ontogeny and evolutionary history. Tinbergen formalized the Lorentzian approach, which till today remains the fundamental research not only in ethology but in entire organismic biology. This basic theory frame was based on concepts by Greek philosopher Aristotle (384–322 BC) and by Scottish Philosopher and Economist David Hume (1711–1776), among others.

In 1970, KL's older brother Albert Lorenz (1885–1970), medical orthopedist doctor and assistant of father Adolf (see A. Lorenz 1952) and mentor of KL died.

In 1971 KL first published a popular book, which was among his most recognized texts: *Civilised Man's Eight Deadly Sins* (1973a), a discussion of human social problems from an (outdated and biologicistic) evolutionary perspective. The book has a strong culture-pessimistic tone, inspired by late German Idealism and by Philosophical Anthropology in the tradition of Arnold Gehlen (1904–1976), German philosopher, anthropologist, and sociologist. This book shows that KL faithfully adhered to his ideas on the "self domestication" of man even after World War II.

In 1973 KL retired from his directorships at the MPI in Seewiesen and returned to Austria. He transferred a free-flying flock of >100 Greylag geese into the Upper Austrian Almtal, near Grünau and the same year established the local Konrad Lorenz Research Station (KLF), hosted by the Duke of Cumberland Foundation. Essentially, he would spend the summers there till his death, in the company of his Greylag geese and collaborators. KL was elected head of the Behavioral Biology section of the Austrian Academy of Sciences which also started moderate funding of the KLF. KL published the foundations of his

“Evolutionary Epistemology,” inspired by a combination of evolutionary theory and Kantian concepts, in his book *Behind the Mirror* (1973b, 1977). On December 10, KL, Niko Tinbergen, and Karl von Frisch were awarded the Nobel Prize for Physiology and Medicine “for their discoveries concerning organization and elicitation of individual and social behaviour patterns”: [https://www.nobelprize.org/nobel\\_prizes/medicine/laureates/1973/lorenz-facts.html](https://www.nobelprize.org/nobel_prizes/medicine/laureates/1973/lorenz-facts.html)).

In 1974 KL built his huge, 34,000 l reef tank in Altenberg with the Nobel Prize money in a building owned by chemist and former Seewiesen assistant Guido Hückstedt. Old KL basically spent his winters writing and observing reef fishes in Altenberg, his summers observing geese in Grünau. Most of his fish work remained unpublished, only parts were published after his death (1998, see below). The aquarium was destroyed after KL had died.

In 1978, KL published his textbook *Vergleichende Verhaltensforschung* (“Comparative Behavioral Biology”), dedicated it to Niko Tinbergen.

In 1979 KL reluctantly accepted his role as a spearhead environmentalist at the forefront of establishing a Green party in Austria. After his bad World War II experiences with the ideological abuse of science he tried to stay off politics, but still took increasing interest in, and responsibility for environmental issues. He had an important role in preventing yet another big hydroelectric power plant at the river Danube, which would have destroyed much wetland and as part of a movement of citizens he had an important role in keeping Austria free of atomic power plants.

In 1981, the Konrad Lorenz Institute of the Austrian Academy of Sciences, with branches in Altenberg and Grünau was established.

KL's wife Margarethe Lorenz died January 16, 1986. Lifelong she was his best friend, his manager, his main partner, critically discussing his manuscripts and not the least, his moral custodian. As a medical doctor she earned the living for her growing family before 1940, when KL was unemployed and concentrated on behavioral research and she was the social backbone of virtually every institute where KL was leading

director. In 1988 KL's last book, a semiscientific monography on Greylag goose behavior was published (Lorenz 1988). However, KL was unable to finish his last project, a monography on the behavior of perciform fishes, intended to integrate his lifetime experience, collected virtually from his cichlid experiments in the 1920s to Moorish idol social ontogeny research in the 1980s.

On February 27, 1989, Konrad Lorenz died at the age of 86 in his Altenberg home.

The Austrian Academy of Sciences stopped funding of the Konrad Lorenz Forschungsstelle in Grünau. Still, this research station survived till today, since 1990 headed by the author of this contribution; it first existed as a cooperation between the local landowner (Duke of Cumberland), the State of Upper Austria, and the University of Vienna. In 2011, the KLF reached University of Vienna Department status. The two other “Konrad Lorenz Institutes” are the “KLI for Comparative Behavioral Biology” at the Vienna Wilheminenberg, founded by Otto Koenig after World War II, later an Institute of the Austrian Academy of Sciences, today part of the University of Veterinary Medicine, Vienna. Finally, there is the privately funded “KLI for evolution and cognition research,” residing first in the Lorenz-Villa in Altenberg, now in an institute building in Klosterneuburg, near Vienna. The Grünau and the Wilheminenberg institutes are dedicated to empirical/experimental behavioral biology till today, the Klosterneuburg Institute remains theoretically orientated.

In all three cases, there is indirect continuity between Konrad Lorenz and his successors. In contrast to Niko Tinbergen, KL initiated no vital and continuous “school” of behavior results, but influenced present day research more indirectly than Tinbergen did. Also, the original intention of the Max Planck society was not fully successful, to establish a group of geniuses around Konrad Lorenz in Seewiesen, and thereby, catalyze an explosion of novel high-class interactive research. This was certainly a highly fertile Institution, but the kind of close cooperation between ingenious researchers and disciplines the MPG had in mind did not fully materialize.

## Achievements: What Remained and What Did Not

KL built his oeuvre on years of systematic observations and experiments. Actually, he frequently advocated “unbiased observation” as a major approach to detect novelty (e.g., 1992) and tended to be skeptical of “testing hypotheses.” He also reacted to the speculative, vitalistic, and behaviorist concepts on behavior of many experimental psychologists and behaviorists in the first half of the twentieth century. Basically valid till today remained the centerpieces of “ethological theory”: As O. Whitman and O. Heinroth before him, KL found that basically innate, stereotyped behavioral elements (“Erbkoordinationen,” i.e., “Fixed Action Patterns”; FAPs) are the core elements in animal behavior, including humans. They are species-specific, hence varying less within than between species. The species-specific shape of the FAPs renders them useful for taxonomic classification (Lorenz 1941b) the same way as anatomical characters in classical taxonomy. Another element of classical ethology is that perception and behavior coevolved like a lock and its fitting key; this “key stimulus” concept holds that many of the FAPs are triggered by specific but generally simple stimuli.

KL together with Erich von Holst found that animals including humans, are not only behaving in response to external stimuli or sensory feedback, but that they may be “spontaneously” active, meaning they respond to internal stimuli, which in sum are called “motivation.” Together with Niko Tinbergen, KL elaborated on the fixed and “taxis” (i.e., orientation) components of FAPs (Lorenz and Tinbergen 1938). In response to, and in development of, Ivan Pavlov’s “reflex chain theory.” KL and others refuted, that individuals are born with “*tabula rasa*” minds and that all behavior(s) would be learned, as, for example, the behaviorist, notably, Frederic B. Skinner (1904–1990) advocated. KL knew that learning would adapt species and individuals to cope with environmental variability, but held that they would be born with innate perception/attention structures. Actually, KL acknowledged that the discussions with D. Lehrman

inspired his “innate schoolmarm” concept (1980), later called “instinct to learn” by Peter Marler. This “innate schoolmarm” orchestrates what is learned and what not. KL described “social imprinting,” notably in Jackdaws and in Greylag goose hatchlings, and he conducted some experiments on the stimuli involved. Still, at the focus of KL’s work were innate, instinctive behaviors (Lorenz 1937), not so much the mechanisms of learning. To this day, the Lorenz-Tinbergian principles remain basic to behavioral biology and biopsychology.

Based on his broad and systematic knowledge of animal behavior in integration with some concepts of Immanuel Kant, KL too laid the theoretical foundations for human ethology. In particular, he made clear, that the human perception and brain and thus, cognitive abilities, must have been selected for their survival value. Thereby, he also contributed to “Gestalt Psychology” and “Evolutionary Epistemology” (“Evolutionäre Erkenntnistheorie”; 1973b, 1992; with University of Vienna-based biologist and philosopher Rupert Riedl 1925–2005 as a major proponent). It also remains a lasting contribution of KL not to see aggression simply as a “social pathology” but as a potentially adaptive motivational/emotional system (1963, 1966). But some of the Lorentzian ideas did not stand the test of time, for example, his concept on the proximate mechanisms of motivation: KL suggested that each behavior (FAP) would have its own, independent drive system. And if a certain action pattern would not be used for a while, “action-specific energy” would build up (KL’s “psychohydraulic model of motivation”) and finally, “spill over.” This may adequately describe the aggressive behavior of a territorial cichlid fish, but it is unsuitable as a general model of motivation of aggression or of other domains of behavior. The general rule of today tends to become the special case of tomorrow, as KL himself frequently put it.

KL tended to overstretch the societal relevance of his behavioral concepts and of the (crude) genetics of his time. This is particularly evident in the context of his lifelong preoccupation with the “self-domestication of man” (e.g., 1971, 1974). KL advocated eugenics in the 1940s, as

many biologists worldwide did at that time. But he publicly regretted this mistake after the war and particularly apologized for his 1940 papers when being awarded the Nobel Prize in 1973. Still, he seemed to remain convinced, that civilization would change selection pressures in a way causing the “genetic degeneration” of mankind. This would lead to a general deterioration of human social behavior. This misled genetic determinism and cultural pessimism in the tradition of Arnold Gehlen remains a problematic part of KL’s legacy, which, however, is not directly connected to his major ethological concepts.

After World War II, KL turned towards the mechanisms of social organization he observed in the animals he had previously employed for establishing the general principles of individual behavior, geese and perciform fishes. Even at the boom times of individual selection, in the late twentieth century, KL remained a convinced group selectionist, opposing, for example, the writings of E.O. Wilson. In contrast to his work before World War II, only little of his late results and thinking were adequately published (see Lorenz 1973b, 1978, 1998). Instead, KL increasingly commented on those developments in society, he was deeply concerned about (e.g., Lorenz 1973a). This made him a “guru”-like figure (he was not really happy with such a role) for generations of environmentalists.

KL was an eminent scientist and a splendid communicator. He made behavioral biology a “real” science (e.g., in contrast to the early twentieth century vitalistic approaches). From early on, KL was convinced that all behavior needs to be explained via the “physicochemical processes in the brain.” Based on the Darwinian principles he made clear, that animal and human psychology are inseparably the same discipline. This kind of synthesis is in fact, reflected in contemporary academia. KL popularized behavioral biology worldwide, particularly, in German-speaking countries.

For an autobiographical sketch highlighting also KLs scientific milestones see [https://www.nobelprize.org/nobel\\_prizes/medicine/laureates/1973/lorenz-bio.html](https://www.nobelprize.org/nobel_prizes/medicine/laureates/1973/lorenz-bio.html)

## K-Reproductive Strategy

D. Susie Lee

Department of Anthropology, New York  
University, New York, NY, USA

## Definition

A K-reproductive strategy is a set of life history traits that would be selected for when a population reaches highest density. The terminology is taken from a parameter in population growth models, where carrying capacity ( $K$ ) is the maximum population size that can be supported by an environment. The opposite strategy is an  $r$  reproductive strategy, after the parameter for the maximum intrinsic rate of natural increase ( $r_{max}$ ) at theoretically zero density.

## Origin of the Concept

The terms  $r$ - and  $K$ -strategy originated from “ $r$ -selection” and “ $K$ -selection,” which were first coined by MacArthur and Wilson (1967). On a

hypothetical island with a starting point of abundant resources, these resources would become limited as the island is fully occupied. Using this example, the authors proposed that different selection regimes would operate as resource limitation experienced by a population changes between two opposing ends of density dependence – low to high density. Under this scenario, high density and thus high level of competition over resources would favor traits that maximize carrying capacity, hence the K-selection.

Pianka (1970) expanded the concept of *r*- and *K*-selection to develop a theory of life history strategies. He considered that the life history of an organism is a position on a continuum between a quantitative extreme (the *r*-endpoint) and a qualitative extreme (the *K*-endpoint). Importantly, Pianka developed a set of predictions for the life history correlates expected under *K*- and *r*-selection. In a high-density environment, *K*-selection would favor traits that allow for organisms to persist in the face of scarce resources such as high competitive ability, delayed maturation, longer lifespan, larger body size, and iteroparity. A suite of opposite traits would be expected under a low-density environment through *r*-selection. These alternative sets of life history traits became known as “*K*-strategies” and “*r*-strategies.”

The idea of *r*- and *K*-selection, and Pianka’s broadening of the idea into life history strategies, have been influential to the study of life history evolution. Most of all, it appealed to the desire to enumerate a simple yet generalizable explanation for life history diversity. Here the degree of density dependence was used as a major axis to explain the covariation of certain life history traits across species. For example, based on an inverse correlation between  $r_{max}$  and body size, Pianka compared insects and vertebrates for their non-overlapping distribution of body size to suggest bimodality in life history traits among relatively *r*- and *K*-selected organisms. Similarly, later studies incorporated the comparative approach for different species or different populations of the same species. But differences in the density experienced by organisms were often only assumed or inferred but not directly tested for its causal contribution to life history differences.

## Current Developments

Numerous empirical and theoretical studies have pointed out the limited applicability of *r*- and *K*-selection theory. First, in experimental evolution studies, fruit flies (Mueller 1988) or pitcher plant mosquitoes (Bradshaw and Holzapfel 1989) bred under high or low densities evolved differences in competitive ability, consistent with MacArthur and Wilson’s predictions. However, their life history traits did not differ by breeding lines as Pianka would predict. Second, mathematical models of selection have shown limitations of the *r*- and *K*-selection theory. For example, the theory assumes that *r* and *K* approximate fitness, but this assumption would be valid only when population growth rates follow the logistic equation and not when we take into account of factors such as population dynamics or age structure. Current theories, including those put forward by Charlesworth (1980) and Stearns (1992), further incorporate age-specific mortality or density-independent factors such as environmental stability to understand the causal link between the environment and an optimal life history. Theoretical consideration has also provided no support for the idea that density-dependent selection will explain the evolution of semelparity vs. iteroparity.

Due to these problems, the theory of *r*- and *K*-selection was gradually replaced by models that describe specific conditions of population density dependence and the magnitude of environmental effects. As accurate measures of these factors are hard to evaluate in natural populations, challenges remain for current paradigms of life history evolution.

## Kyoto

Kazutaka Shinozuka

RIKEN Center for Brain Science, Wako, Saitama, Japan

## Introduction

KYOTO is a prefecture in Japan, located in West-Central Honshu (Kansai region). Previously the capital city of Japan, it has over 2000 temples and shrines and attracts many tourists from all over the world. There are many universities and colleges in Kyoto, including Kyoto University. Kyoto University occupies an important position in the field of animal cognition and evolution in Japan as it established the Primate Research Institute, leaders in Japanese primatology. This entry describes the development of the Primate Research Institute, with a special focus on one of its founders, Dr. Kinji Imanishi.

## Kinji Imanishi (1902–1992)

Kinji Imanishi is considered one of the key founders of Japanese primatology. He began his research studying aquatic insects as a graduate student and received a Ph.D. from Kyoto University in 1939. His thesis, entitled “Mayflies from Japanese torrents,” proposed his original theory of

evolution, based on his studies of Ephemeroptera in the Kamo River in Kyoto (Imanishi 2002). His theory emphasized the society of species and divided organisms into three layers, namely, individual, species, and holospecies. Imanishi considered individuals living in the same niche to have similar characteristics and comprise a species (Matsuzawa and McGrew 2008).

During World War II, Imanishi went to Mongolia and began to study mammalian society in wild horses and nomadic people. After the war, he returned to Japan and continued to study horse society in Misaki-uma, a breed of semi-wild horse, in Cape Toi, Miyazaki Prefecture. During this project, Imanishi and his colleagues met a group of wild monkeys and decided to study the society of monkeys, beginning with wild Japanese monkeys on Koshima Island, Miyazaki Prefecture, in 1948. Imanishi went on to study wild monkeys at 19 sites in Japan, including Yakushima and Takasakyama, over the next 7 years. He emphasized that the social systems in human society may just be an institutionalization of a primate-like ancestor’s social systems and proposed a primatological approach to analyzing human social systems (Nishida 1984).

Imanishi also developed a novel method for observing animal society: individual identification, habituation to humans (including provisioning), and long-term observation. These methods are now commonplace and often used without reference to Imanishi, so that de Waal (2003) called his achievement a “silent invasion.” Using these methods, Imanishi and his colleagues revealed several interesting aspects of Japanese monkey society, including the culture-like transmission of sweet potato washing behavior (Kawai 1965).

In 1956, researchers from Kyoto University and the University of Tokyo (including Imanishi) established the Japan Monkey Center (JMC) at Inuyama, Aichi Prefecture, with the cooperation of the Nagoya Railroad Co., Ltd. The JMC aimed to promote primate research, education, conservation, welfare, and public education regarding non-human primates. Initially it comprised a research department, a zoo, and an amusement park. The JMC also launched the international scientific

journal *Primates* in 1957, which is the oldest journal in primatology and one of the most popular.

In 1958, the research department dispatched Kinji Imanishi and Junichiro Itani to Africa, where they conducted research in Kenya, Uganda, Congo, and Cameroon, among other locations. The Japanese team started to study wild chimpanzees at Mahale in 1965, in parallel with Jane Goodall's study at Gombe.

The JMC research department was abolished in 1976, affected by the establishment of the Primate Research Institute next to the JMC. The amusement park was detached when it became unprofitable, and the JMC became a Public Interest Incorporated Foundation in 2014. Tetsuro Matsuzawa, a former director of the Primate Research Institute at Kyoto University, described Imanishi's achievements as follows: (1) providing an equitable and harmonious "holistic" viewpoint for understanding the world of organisms, (2) supporting this viewpoint by conducting field research in nonhuman primates, and (3), as a result of establishing "primatology," enhancing the development of a range of related research fields including morphology, genetics, psychology, and physiology (Matsuzawa and McGrew 2008).

## The Primate Research Institute at Kyoto University

In tandem with the development of primatology led by Imanishi and his colleagues, in 1964 the Science Council of Japan recommended the establishment of a national primate research institute to the Cabinet of Japan. In response to the recommendation, Kyoto University established the Primate Research Institute (PRI) adjacent to the JMC at Inuyama, Aichi Prefecture, in 1967. In 1975, the PRI completed the nine sections proposed in the original plan. Initially most of the researchers, aside from those in the morphology, society, and life history sections, were from outside primatology; their backgrounds were diverse, including agricultural science, veterinary medicine, human medicine, and literature. Through intense

discussion, they shared the central proposition of the PRI to develop an overall picture of primates and better understand human origin (Sugiyama 1985).

## Ai Project

"Ai," a wild-born 1-year-old female chimpanzee from the Guinean Forest in West Africa, arrived at the PRI in 1977. Soon after that, "Akira," a 1.5-year-old male, and "Mari," a 1.5-year-old female, also arrived at the Institute (Matsuzawa 2003). Following on from the success of other researchers' studies with chimpanzees such as Washoe (Gardner and Gardner 1975), Sarah (Premack 1971), and Lana (Rambaugh et al. 1973), the Ai project investigated artificial language acquisition in chimpanzees. The Ai project used the KU (Kyoto University) lexigram presented on a computer-controlled apparatus. Importantly, the study was conducted not as an "acquisition of language" study but as a "symbolic matching to sample" task, allowing researchers to analyze its acquisition and generalization in a descriptive and objective manner (Matsuzawa 2003). Three chimpanzees including Ai successfully learned naming of objects and colors. They could use combinations of corresponding lexigrams to answer a presented object and its color (Asano et al. 1982). Researchers also found that chimpanzees had difficulty generalizing a learned relationship in the opposite direction without appropriate training (Kojima 1984; e.g., they could learn to choose B when A was presented, but had difficulty generalizing to choose A when B was presented). Ai also learned to discriminate 26 letters of the alphabet as a test of shape perception and visual acuity and Japanese Kanji characters expressing different colors for classification of colors (Matsuzawa 2003). The Ai project started to focus on recognition of number concepts in chimpanzees when Ai was 5 years old (Matsuzawa 2009). First, Ai mastered numerical naming of items in a display ranging from one to six (Matsuzawa 1985). Then, she mastered ordering numerals from zero to nine (Biro and Matsuzawa 1999). Even when all

numbers were masked after touching the first number, Ai demonstrated an impressive ability to touch the masked numbers in the correct sequence, indicating a capacity to remember the sequence of numbers comparable to that of humans (Kawai and Matsuzawa 2000; Inoue and Matsuzawa 2007).

In 2000, three chimpanzees (Ai, Chloe, and Pan) produced offspring via natural copulation. The PRI researchers began to study cognitive development in chimpanzees. To investigate infant chimpanzees' natural social/cognitive development, infants were reared not by humans, but by their mothers in a community with other chimpanzees. Studies investigated a range of developmental indicators, including recognition of the mother's face, mutual gaze between mother and infant, gaze following, and triadic interactions, and compared the chimpanzee infants' results with human infants (Tomonaga et al. 2004). Chimpanzee infants showed comparable responses to human infants except for triadic interactions between mother-infant-object. At 1 to 2 years old, chimpanzee infants often watched the mother manipulate a novel object and then tried to manipulate it themselves. This triadic interaction differs from that of humans, because the chimpanzee infant seldom looked back at, showed the object to, or gave the object to the mother. Furthermore, the chimpanzee mothers did not show or give the object to the infants (Tomonaga et al. 2004).

### Activities for Chimpanzee Conservation

Researchers at the PRI also put their heart into chimpanzee conservation. Since 1997, they have been working in cooperation with the Institute for Environmental Research at Bossou and local villagers, and with the support of the Japanese Embassy in Guinea, the Guinean government, and various international organizations, to establish a green corridor. The green corridor consists of trees planted along a 300-m-wide and 4-km-long stretch of savanna running between Bossou and the Nimba Mountains, to

re-establish migration of chimpanzees between the Bossou and Nimba populations (Matsuzawa et al. 2011; Green Corridor Project website: <https://www.greencorridor.info/en/green-corridor/>).

In 1998, researchers mainly at the PRI founded "SAGA" (Support for African/Asian Great Apes) to (1) conserve the natural habitat of wild great apes, (2) enrich the lives of those in captivity, and (3) bring an end to the use of great apes as subjects in invasive studies (SAGA website: <https://www.saga-jp.org/indexe.html>). At that time, there were 388 chimpanzees in Japan, including 138 individuals used for invasive biomedical research by pharmaceutical companies. In 2006, all invasive biomedical research on chimpanzees in Japan was stopped completely. All chimpanzees formerly involved in biomedical research have been retired and are comfortably housed at Kumamoto Sanctuary, run by Kyoto University (SAGA website). SAGA also emphasizes the importance of maternal rearing, not human rearing, to give normal social experiences for chimpanzee infants. Experience of maternal rearing in infancy is very important for normal social development and expression of appropriate parental behavior toward offspring in adulthood. Human rearing should be avoided, except temporary separation for medical reasons (Matsuzawa 2016). SAGA has repeatedly issued statements against the inappropriate rearing and exhibition of chimpanzees (SAGA website).

### Wildlife Research Center at Kyoto University

In 2008, Kyoto University established the Wildlife Research Center, to promote scientific research and education on wild animals. Its missions are (1) to conduct basic research on endangered and threatened species of wild animals, (2) to integrate different areas of science to create new disciplines applicable to field settings, and (3) to collaborate with zoos, sanctuaries, aquariums, and museums to promote youth environmental education (the Wildlife Research Center website: <https://www.wrc.kyoto-u.ac.jp/en/index.html>). Administration of the Koshima and

Yakushima field stations was transferred from the PRI to the Wildlife Research Center. The Center also includes the Kumamoto sanctuary for chimpanzees. In addition to primates, the Center also conducts studies on other species including elephants, dolphins, and seals, in cooperation with zoos and aquariums in Japan. Today, both the concepts and methodology of primatology founded by Kinji Imanishi and his colleagues in Kyoto are engrained in the field and utilized globally.

## Laboratory Research

Sangeeta Panicker  
American Psychological Association,  
Washington, DC, USA

Knowledge about animals can be gained through research conducted in naturalistic settings as well in captive settings such as zoos, sanctuaries, and laboratories. The type of knowledge that can be gained in these different settings also varies because of the limitations inherent to each setting. For example, observational research conducted in naturalistic settings provides information about the species' behavior in its natural habitat, while similar research in zoos, sanctuaries, and laboratories contributes to our understanding of the core cognitive or learning processes that give rise to the same behavior, although it may be differently manifested in captive settings. Gaining a deeper scientific understanding of a species' behavioral and cognitive abilities including their underlying biological bases, developmental processes, and social influences often requires a controlled environment – an environment that allows for a systematic assessment of different factors on specific behaviors. Such control can be achieved neither in the animals' natural habitats nor in captive settings such as zoos and sanctuaries. Rather, it requires the study of animals, most of which are specifically bred for research in a laboratory setting, where scientists can control genetic, dietary,

social, and other environmental factors that affect behavior and cognition. Methodologies used in laboratory-based studies range from simple observations of animals' behaviors to more complex designs that include manipulating the animal's environment and measuring behavioral outcomes as well as effects on physiological factors such as blood sugar, hormones, and other neurochemicals.

Reliability of research findings depends not only on sound scientific methodology but also on appropriately maintained research animals. A formal system of regulatory oversight of animal research, in the USA, is just over 50 years old. Long prior to the federal system, the research community recognized the value of knowledge that can be gained through laboratory-based animal research and the importance of standards for animal treatment, as is evidenced by the long history of various professional societies addressing the well-being of laboratory animals through the adoption of standards and codes of conduct (see Table 1).

## Federal Oversight

In the USA today, laboratory animal research is a highly regulated activity and involves oversight at multiple levels by different entities. At the federal level, the US Department of Agriculture (USDA) is charged with enforcement of the Animal Welfare Act (AWA), which Congress passed in

ILAR is now responsible for the periodic update of <i>The Guide</i> |
| 1963 | ACP published the first edition of <i>The Guide</i> . The most recent revision of <i>The Guide</i> was in 2011                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                            |
| 1964 | ACP tests a pilot program for inspecting and accrediting animal research facilities                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                       |
| 1965 | American Association for Assessment and Accreditation of Laboratory Animal Care, AAALAC (now called AAALAC International) established                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                     |
| 1966 | Laboratory Animal Welfare Act (AWA) enacted. It has been amended eight times, with the most recent amendment in 2013                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                      |
| 1971 | First NIH Policy on Care and Treatment of Laboratory Animals applicable to institutions that receive NIH funding for research with warm-blooded animals                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                   |
| 1973 | First Public Health Service (PHS) Policy is issued – <i>Principles for Use of Laboratory Animals</i> – it applied to all vertebrate animals                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                               |
| 1985 | Health Research Extension Act is enacted and provides statutory basis for the PHS Policy<br>AWA amendments pertaining to research passed by Congress – requiring institutions to (1) provide training for all personnel involved in the care and use of animals in research, (2) conduct semiannual inspections of animal research facilities, (3) attend to the psychological well-being of nonhuman primates in research, and (4) provide exercise for research dogs<br>An Interagency Research Animal Committee promulgates the <i>US Government Principles for the Utilization and Care of Vertebrate Animals Used in Testing, Research, and Training</i>                                                                                                                                                                                                                                                                                             |
| 1986 | Final version of the <i>PHS Policy on Humane Care and Use of Laboratory Animals</i> went into effect, incorporating provisions mandated by the Health Research Extension Act of 1985                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                      |

1966 (Animal Welfare Act of 1966, 2013). The AWA regulates the care and treatment of certain animals that have been bred for sale, for research, or for public exhibition, thus covering animals in a range of settings that include not only dedicated research facilities but also zoos, sanctuaries, entertainment, breeders, and dealers. AWA includes requirements for animal husbandry, handling, housing, nutrition, sanitation, ventilation, and veterinary care.

Within the USDA, the Animal and Plant Health Inspection Service (APHIS) Animal Care Unit is responsible for the oversight of laboratory animal research. All research facilities that support research with animals covered by the AWA are required to register with APHIS. APHIS fulfills its oversight responsibilities through annual inspections of registered research facilities. The AWA and ensuing regulations cover research conducted with live or dead dogs, cats, nonhuman

primates, guinea pigs, hamsters, rabbits, or other warm-blooded animal except rats of the genus *Rattus*, mice of the genus *Mus*, and birds specifically bred for research.

While research with rats, mice, and birds is not regulated by the USDA under the AWA, the enforcement of standards for the humane care and treatment of these species in research falls within the purview of other federal agencies, including the National Institutes of Health (NIH) Office of Laboratory Animal Welfare (OLAW). OLAW implements the Public Health Service (PHS) Policy on Humane Care and Use of Laboratory Animals (PHS Policy) (Public Health Service Policy on Humane Care and Use of Laboratory Animals 1986). The PHS Policy applies to all live vertebrates used or intended for use in PHS-funded research as well as research funded by the National Science Foundation (NSF).

The Health Research Extension Act of 1985 (Health Research Extension Act 1985) provides the statutory basis for the enforcement of the PHS Policy for PHS-funded research with animals. The PHS Policy requires institutions to use the standards described in *The Guide for the Care and Use of Laboratory Animals (The Guide)* (National Research Council 2011) as the basis for developing and implementing their animal care and use programs. That same year, Congress also amended the AWA to specifically address issues related to improving standards for the humane care and treatment of laboratory animals. In addition, the 1985 AWA amendments included a provision mandating the Secretary of the Department of Agriculture to coordinate with the Secretary of the Department of Health and Human Services on the promulgation of specific requirements under the AWA. Finally, also in 1985, a federal Interagency Research Animal Committee promulgated the US Government Principles for the Utilization and Care of Vertebrate Animals Used in Testing, Research, and Training (US Government Principles) (Office of Science and Technology Policy 1985), which was adopted by all US federal agencies that conduct or support research with vertebrate animals. The US Government Principles provide a framework for conducting research that complies with both the AWA regulations and the PHS Policy.

OLAW meets its regulatory mandate by requiring institutions that receive PHS funding for research to have an OLAW-approved Animal Welfare Assurance before conducting any research involving vertebrate animals. In the Assurance, the institution attests to compliance with all relevant regulations, the US Government Principles and the PHS Policy. The Assurance also provides detailed information about the institution's animal care and use program, its Institutional Animal Care and Use Committee (IACUC), and an inventory of the species housed at the institution. Similar to the APHIS, OLAW delegates oversight responsibility at the local level to the IACUC, which reviews and approves proposals for research with animals, and submits an annual report to OLAW certifying that semiannual inspections were completed and report serious noncompliance, if any. OLAW evaluates all allegations of noncompliance and conducts approximately ten not-for-cause site visits of assured institutions. The Office also offers education programs focused on sustaining research animal well-being.

## Public Transparency

Federal laws, such the Freedom of Information Act (FOIA) as well as state sunshine laws, provide the general public with access to information regarding research regulated by the USDA and OLAW. Public transparency of the oversight process includes access to USDA and OLAW records, including annual facility reports of the number of animals housed and number involved in research, semiannual inspection reports, and reports of noncompliance, if any.

## Nongovernmental Oversight

In addition to oversight by federal bodies such as APHIS and OLAW, institutions that support animal research programs can choose to be accredited by a private entity, AAALAC International (formerly known as the Association for Assessment and Accreditation of Laboratory

Animal Care International). AAALAC International assesses the institution's animal research program not only to ensure compliance with all relevant federal, state, and local regulations and policies but also the extent to which the animal care and use program meet or exceed the standards set forth in *The Guide*. Institutions that obtain AAALAC International accreditation are required to submit an annual report that provides AAALAC International with up-to-date information on the institution's animal care and use program. AAALAC International conducts site inspections every 3 years to determine whether the institution can maintain its accreditation status. As a private entity, AAALAC is not subject to public records requirements.

### Local Oversight

Both the AWA regulations and PHS Policy assign primary accountability for research animal well-being to the institution through the establishment of an Institutional Animal Care and Use Committee (IACUC). Per the AWA regulations, an IACUC at a USDA-registered facility should consist of, at minimum, three members and include a chairperson, a laboratory animal veterinarian, and a community representative who is unaffiliated with the institution. IACUC functions include a semiannual review of the institutions' program for the humane care and use of animals and a semiannual inspection of the institution's animal facilities. The IACUC is responsible for reporting the findings of its reviews and inspections to the responsible institutional official, noting both minor and significant deficiencies in the program, if any. In the case of significant shortcomings, the IACUC should provide a time line for addressing the identified deficiencies. If the deficiencies are not addressed within the specified time frame, then the IACUC is required to report it to APHIS within 15 days of the lapsed deadline.

The IACUC at an OLAW-assured institution is mandated by PHS Policy to have a minimum of five members – a chairperson, a laboratory animal veterinarian, an affiliated community representative, a scientist with animal research experience,

and a nonscientist. The IACUC must submit an annual report to OLAW detailing any changes to the animal care and use program at the institution, the institution's AAALAC accreditation status, IACUC membership, and dates of its semiannual reviews of the institution's animal care and use program and its animal facilities. The IACUC is responsible for promptly reporting to OLAW any serious or continuing noncompliance with the PHS Policy, serious deviations from *The Guide*, and the suspension of any activity by the IACUC. OLAW provides IACUC with detailed guidance on fulfilling its duties.

### IACUC Protocol Review Criteria

In addition to the semiannual reviews and inspections of the institution's animal research program, a major function of the IACUC is to review and approve proposals for the conduct of research studies involving animals. The IACUC is responsible for implementing federal policies as well as state and institutional policies that might be more stringent than federal requirements.

Before approving proposals, the IACUC reviews and documents that the proposed study is not duplicative and that the researcher has considered alternatives to the use of animals for the proposed study. Thus, the protocol must contain a written narrative that describes the research literature as well as the outcome of searches for alternatives on specific databases. The IACUC also ensures that the researcher has described steps that will be taken to minimize any pain and distress, if any, to the animals and how research procedures that involve more than momentary pain and severe or chronic pain or distress will be handled. In addition, the proposal must provide evidence that all research procedures will be conducted by appropriately trained and qualified personnel. The IACUC must ensure that clearly specified requirements for procedures involving surgery are met and that no animal is used in more than one major operative procedure, unless scientifically justified. The IACUC also must evaluate the appropriateness of species for the proposed study and the number of animals required to

obtain scientifically valid results. And lastly, the IACUC ascertains that the animals' living conditions are appropriate. Although assessing the scientific merit (peer review) of proposed research is not within the purview of the IACUC, it is responsible for judging the scientific relevance of the proposed research including its potential to contribute to the health of humans or other animals, to the advancement of knowledge, and/or to the good of the environment or society in general.

In conclusion, laboratory-based research with animals is subject to much more stringent and rigorous oversight than any other activity involving animals, including similar research conducted in other settings such as zoos, sanctuaries, and the wild.

## Lagomorpha Diet

Barbara Toddes  
Nutrition Program Director, Philadelphia Zoo,  
Philadelphia, PA, USA

## Introduction

Within the order *Lagomorpha* there are two living families, the *Leporidae* which include hares and rabbits and *Ochotonidae* which are the pika. There are 63 species in the *Leporidae* family, while in the *Ochotonidae* family there are 28 species. Rabbits and hares are often thought of as one group of animals – yet they are actually quite different. Both are considered mid-sized herbivorous mammals and hind gut fermenters – but their general habitat and natural food selection differs (Mišta et al. 2015). Rabbits are generally smaller than hares, the pygmy rabbit is the smallest rabbit weighing only 300 g while the European hare is the largest hare and can weigh as much as 5 kg. There are 30 species of hares and they all belong to the same genus *Lepus*; whereas, there are 10 different genus of rabbits (Caravaggi 2018).

## Digestive Morphology

### Teeth

Lagomorphs possess long-crowned (hypsodont), continuously growing (elodont), and open-rooted (aradicular) teeth. This continuous growth is not constant but compensates for the wear of the respective tooth and is an evident adaptation to compensate for tooth wear (Vella and Donnelly 2012). The rates of wear and growth must match in ever growing teeth in order to maintain proper occlusion (Muller et al. 2014). Lagomorph dentition is heterodont or functionally different types of teeth. Lagomorphs have what is known as diphyodont dentition, which means they have deciduous (primary) and secondary (adult) teeth. Rabbits have 16 deciduous teeth and 28 permanent (secondary) teeth (Rabbit Teeth – Problems & Anatomy of Rabbit Teeth – Veterinary Dentist Wisconsin, Minnesota n.d.). Rabbits and hares have 28 teeth, pika have 26. The dental formula for rabbits and hares is  $2.0.3.3/1.0.2.3 = 28$  (Van Caelenberg 2008). The dental formula for pika is  $2.0.3.2/1.0.2.3 = 26$  (Smith et al. 2018). Tooth growth is strongly related to tooth wear. Rabbit's tooth wear is very dependent on the diet and the tooth position (Muller et al. 2014). While lagomorphs and rodents each have large diastemas (the gap between the incisors and the molar teeth), the lagomorph small peg-like incisors, without a cutting edge, lie immediately behind the larger first incisors – this characteristic distinguishes them from rodents (Smith et al. 2018).

Lagomorphs are generalized herbivores and possess a very large gut that houses bacteria to aid in the digestion of cellulose (Smith et al. 2018). The digestive tract of *Lagomorpha* is comprised of a single-chamber glandular stomach with a well-developed fornix, a long cecum with lymphoid formations and a deep spiral fold, and a colon forming a number of muscular pockets. The large intestine of pikas is more complicated and differentiated than that of hares and rabbits (Naumovaa et al. 2014).

Both families *Leporidae* and *Ochotonidae* have a colonic separation mechanism. When the separation mechanism diverts fine particles into

the caecum, only large food particles are passed and the animal produces hard faeces. When the mechanism is not functioning, fermented caecal materials are excreted as soft faeces. These soft faeces are rich in vitamins and microbial proteins and are reingested. During the daytime, both soft and hard faeces are defecated and all of the faeces are reingested. At night, the animals only excrete hard faeces – which tend not to be reingested unless the animal is starving. Hard faeces are basically a refuse, when daytime hard faeces are reingested the animal will thoroughly masticate the large particles to fine ones that are then good for fermentation. The regular reingestion of daytime hard faeces thus improves food digestibility and nutrient utilization (Hirakawa 2001).

### Diet

All of the lagomorphs are herbivores; the breadth of the diet varies between species and depends on local environmental conditions and relative availability of food item (Caravaggi 2018).

Pikas are very small mammals only weighing 120–300 g (Ge et al. 2013). Pikas live in mountainous regions in the northern hemisphere (Matthee 2009). Only three species of pika live outside of Asia, two species in Europe, and one species in the United States. Pikas are generalized herbivores; they forage on nearly all vegetation found within their habitat. Berries, seeds, shrubs, buds, grasses, mushrooms, lichens, leaves, and shoots are consumed when they are available, with green parts of available vegetation constant in their diet year-round (Smith et al. 2018). A study of wild plateau pika (*Ochotona curzoniae*) showed a relationship between altitude and diet as well as the diversity of plants included in the diet at different altitudes. The dominant plants in the wild diet of plateau pika is locoweed (*Oxytropis kansuensis*) (Li et al. 2016) which is interesting because this weed contains swainsonine which is known to be toxic to livestock and is believed to cause apoptosis in brain cells (Lu et al. 2013). A general review of the common plants found in the diet of different species of pika can be found in

*Lagomorphs – Pika, Rabbits and Hares of the World* (Smith et al. 2018).

An important distinction between the rabbits and the hares is their reproductive mode. Rabbit kittens are born naked (altricial) following a relatively short period of gestation. Their eyes open about 4–10 days following birth. In contrast, hare leverets are generally well developed (precocial) at birth. Gestation in hares is longer, and leverets are born fully furred with their eyes open. It is also important to note that the common names for some species within the Leporidae are deceptive. For example, the hispid hare (*Caprolagus hispidus*) is a rabbit, and jackrabbits are hares (genus *Lepus*) (Smith et al. 2018).

Rabbits tend to live in forest or shrub areas and dig burrows in the ground for their nests. The herbivorous diets of rabbits reflect their environment. The 2010 publication *Nutrition of Rabbits* (de Blas and Wiseman 2010) provides an excellent and thorough review on the digestion, nutrition, and feeding behaviors of domestic rabbits. This book also includes a chapter on the feeding and nutrition of pet rabbits. A general review of the common plants found in the diet of different species of wild rabbit can be found in *Lagomorphs – Pika, Rabbits and Hares of the World* (Smith et al. 2018).

Hares tend to live in open areas and have simple ground nests, they can be found in a variety of habitats, from dry, hot deserts to the Arctic tundra (Caravaggi 2018). The herbivorous diet of hares also reflects their environment. A general review of the common plants found in the diet of different species of hares can be found in *Lagomorphs – Pika, Rabbits and Hares of the World* (Smith et al. 2018). An interesting study published in the journal *Folia Zoologica* on European hares revealed that individual animals appear to have dietary preferences (Katona and Altbäcker 2002).

Although we have studied and know a great deal about the nutrient and dietary needs of many lagomorph species, there is still a great deal we need to learn. An example is the endangered volcano rabbit (*Romerolagus diazi*) from south Mexico. This animal has a very limited and fragmented range (Caravaggi 2018). Volcano rabbits depend on three species of native grasses:

*Festuca amplissima*, *Muhlenbergia macroura*, and *Stipa ichu*, feeding on the young leaves of grasses and some spiny herbs. Nutrient analysis of these grasses show, at the typical intake of the rabbit, they are inadequate to provide the nutrition necessary to maintain the stable body condition observed in most wild populations. Other plant species, that we are yet unaware of, must complement the diet (Smith et al. 2018). This is only one example of the work needed to more fully understand the nutritional needs and forage selectivity of endangered lagomorphs in order to ensure their habitat can support them.

## Conclusion

There are around 91 living species of lagomorph, many are classified as threatened (vulnerable, endangered, and critically endangered) by the International Union for Conservation of Nature (2017) and/or are Evolutionary Distinct and Globally Endangered (EDGE) species (Fontanesi et al. 2016). Lagomorphs have a global distribution; representative species can be found on every continent with the exception of Antarctica. The habitat requirements for each species vary considerably and some species have very specific environmental needs.

## Lagomorpha Life History

Anthony Caravaggi

School of Biological Earth and Environmental Sciences, University College Cork, Cork, Ireland  
School of Biological Sciences, Medical Biology Centre, Queen's University Belfast, Belfast, UK

## Synonyms

Growth; Hare; Leporid; Longevity; Pika; Rabbit; Reproduction

## Definition

Mammalian life history traits include length of gestation, size and number of offspring, growth patterns, weaning age, timing of sexual maturity, adult body mass, reproductive lifespans, individual longevity, population density, and group composition and size (Jones et al. 2009).

## Introduction

The term “lagomorph” describes species of the mammalian order Lagomorpha (lit: “hare-form”), which is made up of two families, the hares and rabbits (Leporidae; also known as leporids) and the pikas (Ochotonidae). These two groups are united by shared morphological traits which are unique among extant mammals, including several aspects of cranial anatomy and a circulatory channel running through the heel bone (Fostowicz-Frelik and Meng 2013). The evolutionary history of lagomorphs is not clear, though

ongoing research continues to shed light on the origins of the order. Leporids and pikas diverged in the Eocene, around 40 million years ago (mya), a split which may have been facilitated by abrupt changes in climate. Lagomorphs were certainly more diverse than they are in the present, with over 230 species from over 75 genera represented in the fossil record. Pikas initially diversified much more rapidly than leporids, but, over time, this situation was reversed and there are now fewer species of pika, which occupy a far smaller overall area, than there are of hares and rabbits. In addition to genetic differences, the families are easily distinguished visually by comparative morphology (Fig. 1 and subsections herein).

There are around 91 living species of lagomorph, many of which are classified as threatened

(vulnerable, endangered, and critically endangered) by the International Union for Conservation of Nature (2017) and/or are Evolutionary Distinct and Globally Endangered (EDGE) species (Fontanesi et al. 2016). The order has a global distribution, with representative species being found on every continent with the exception of Antarctica, from between the equator and 80°N and between 0 and 5000 m above sea level (Fontanesi et al. 2016). Habitat requirements can vary considerably, with some species being more specific in their requirements and, hence, having a more limited distribution than others. For example, volcano rabbits (*Romerolagus diazi*) are an endangered species found in four volcanoes in southern Mexico which, even within their limited, fragmented range, have a strong preferences for

**Lagomorpha Life History, Fig. 1** Photographic examples of (a) hare, Indian hare (*Lepus nigricollis*; photo by N. A. Nazeer); (b) rabbit, mountain cottontail (*Sylvilagus*

*nuttallii*; photo by USFWS Mountain-Prairie; (c) pika, American pika (*Ochotona princeps*)

subalpine habitats, particularly pine forests (Velazquez and Heil 1996). In contrast, the European hare (*Lepus europaeus*) can utilize a wide range of habitats; it has a broad distribution in its natural range and has been successfully introduced to a number of countries and islands, worldwide (Flux and Angermann 1990).

Lagomorphs have considerable ecological, scientific, and economic importance as they are human food sources, agricultural pets, quarry for field sports, model laboratory animals, and significant components of ecological systems and processes (Chapman and Flux 2008; Fontanesi et al. 2016). These mammals feature prominently in the diets of many predators, with annual mortality rates of up to 80–90% in some species. Fortunately, all lagomorphs have short gestation periods, newborns grow rapidly, and there is little maternal investment in the young after weaning. This means that they are often highly fecund, producing multiple litters of several young, per year (Table 1).

All of the lagomorphs are herbivores; the breadth of the diet varies between species and depends on local environmental conditions and relative availability of food items. With a diet rich in tough cellulose, these mammals have solved the problem of cellulose digestion by utilizing hindgut fermentation and reingestion of first-feces (coprophagy), soft black pellets known as caecotrophs. The secondary digestion allows lagomorphs to further digest the plant matter and maximize nutrient extraction.

Here I give an overview of differences in life history traits between the leporids (subdivided into hares, and rabbits) and pikas, illustrating the variation in the order. While this text details a number of species, there are many for which we have few life history data (Jones et al. 2009).

## Hares

Hares are the most diverse of all the lagomorphs, comprising 32 species, all of which occur within a single genus, *Lepus* (ITIS 2017). The genus contains several species which are commonly known as jackrabbits, e.g., the Tehuantepec jackrabbit

(*L. flavigularis*). They are all, however, true hares. Hares are generally the largest of the lagomorphs, weighing between 2 and 5 kg and are readily distinguished from rabbits by their long ears and hind legs. Their long legs allow them to run at extremely high speeds to escape predators; both the antelope jackrabbit (*L. alleni*) and the European hare have been recorded at 72 kmh (Garland 2009), and it is likely that other large hares can attain similar speeds. The cost of high-speed flight can be substantial, however, and hares will often remain in their forms until a predator is almost within striking distance before fleeing.

Hares can be found in a variety of habitats, from dry, hot deserts to the Arctic tundra. Across their range, they display an array of physiological and behavioral adaptations which have allowed them to thrive. For example, the ears of the antelope jackrabbit, which is found in arid regions of Arizona and Mexico, are extremely large and have an abundance of blood vessels, helping the animals to dissipate heat while minimizing water loss (Dawson and Schmidt-Nielsen 1966). In contrast, those of the mountain hare (*L. timidus*), an arcto-alpine species complex with a circumpolar distribution which inhabits uplands and northern latitudes, are much smaller and heavily furred to reduce heat loss. Hares also molt their coats, from a relatively thin summer coat to thicker, insulating winter pelage and vice versa. In some species such as the European hare in which the summer coat is a light brown compared to the reddish-brown winter coat, there are few obvious differences between seasons. Others, such as mountain hares, go from brown in the summer to white in the winter. This seasonal change confers additional protection from predators via camouflage with snowpack, though the trait has limited plasticity, meaning that white animals at the southern edge of the species range will become increasingly vulnerable as snow cover recedes under climate change (Zimova et al. 2014).

The majority of hare species are largely solitary, only coming together during the breeding season. However, some species such as the Arctic hare (*L. arcticus*) can be highly social, resting and feeding in groups which may number dozens of individuals. The mating behavior of hares is,

**Lagomorpha Life History, Table 1** Selected life history information for 30 of the 90 extant species of lagomorphs. The data describe ranging behavior (home range), breeding ecology (gestation length, litter size, and litters per year),

and growth (neonate body mass, adult body mass). Species are sorted alphabetically according to their Latin names (Data were derived from Ernest 2003, IUCN 2017, and Jones et al. 2009)

DD data deficient

broadly speaking, very similar across the genus. Males aggregate around receptive females, which they will regularly chase at high speeds, and actively compete to establish a dominance hierarchy. Direct competition occurs in the form of “boxing,” the hares rearing up on their hind legs and striking with forepaws, as well as striking with the hind legs while on all fours. Females, which are dominant, also use boxing, as well as grunts and aggressive body language to fend off amorous males (Chapman and Flux 1990).

Most hare species favor an open landscape featuring sufficient cover for rest and offering protection from predators. There are a number of exceptions, including the Manchurian hare (*L. mandshuricus*) which inhabits forests in north-eastern China and Russia (Loukashkin 1943), and the snowshoe hare (*L. americanus*), which inhabits successional boreal forests, swamps, and transitional habitats (Flux and Angermann 1990). The snowshoe hare also demonstrates the importance of many lagomorphs to trophic food

webs as the abundances of avian and mammalian predators and secondary prey species fluctuate in accordance with the snowshoe hare’s 10-year population cycle (Krebs et al. 2001). Hares are largely nocturnal and/or crepuscular, feeding at night and during hours of twilight and resting during the day. These patterns often show seasonal variation, however, with activity commencing before sunset and ceasing after sunrise (i.e., during hours of daylight) when days are longer (Schai-Braun et al. 2012). Hares have among the largest home ranges of the lagomorphs; home ranges for antelope jackrabbits average 4.5 km<sup>2</sup>, and most hares have ranges in excess of the largest found among rabbits (Table 1).

The length of the breeding season varies according to a number of factors including day length and ambient temperature; some species have breeding seasons which last for over 250 days of the year. Reproductive patterns vary by latitude, with larger litters occurring during the shorter breeding seasons in the north. Hares

generally have litters of two to four young (Table 1), although litters as small as one and as large as six have been recorded in some species, and several litters may be produced each season (Rioja et al. 2011). They do not dig burrows or holes in which to give birth, instead creating a depression in the ground, known as a “form,” which is sometimes covered with grass or other vegetation. Young hares, or leverets, are born precocial; their eyes are open, they are fully furred, and they are capable of independent movement soon after birth. This is in contrast to rabbits, which are born much earlier in development (see *Rabbits*). Females place leverets under vegetation such as trees and shrubs (Arctic hare) or grass (Cape hare, *L. capensis*) to hide them from predators. Leverets are nursed once per day with highly concentrated milk. Early offspring survival (i.e., survives the first 3 weeks) is usually between 40% and 50% (Rioja et al. 2011). The average lifespan of a wild hare is between 4 and 7 years.

## Rabbits

The rabbits comprise 29 species across ten genera (*Brachylagus*, *Bunolagus*, *Capolagus*, *Nesolagus*, *Oryctolagus*, *Pentalagus*, *Poelagus*, *Pronolagus*, *Romerolagus*, *Sylvilagus*). Some species are referred to as “hares,” for example, the Natal red rock hare (*Pronolagus crassicaudatus*), though all of the aforementioned species are true rabbits. The most speciose of these are the New World cottontails (*Sylvilagus* sp.), with 17 extant species (ITIS 2017). Rabbits are a diverse group, ranging from species of uplands like the Appalachian cottontail (*S. obscurus*), to dense tropical forest like the Sumatran striped rabbit (*N. netscheri*), to swamps like the semiaquatic swamp rabbit (*S. aquaticus*). Their ranges vary considerably, for example, the European rabbit (*O. cuniculus*), historically restricted to the Iberian Peninsula, has been introduced to a large number of countries and islands and so is one of the most widely distributed mammalian species. In contrast, many other species, including members of more primitive genera such as *Caprolagus*, *Pentalagus*, and *Nesolagus*, many

of which are endangered, are restricted to small habitat patches and/or islands (Alves et al. 2008).

Rabbits are generally smaller than hares, weighing 0.5–2 kg (Table 1). Like hares, they also have large eyes and long ears and back legs, though both are shorter in rabbits. Unlike hares which rely on speed and endurance to evade predators, rabbits generally move in swift, darting movements, relying on burrows and/or vegetation for protection. However, most species are far from ponderous; cottontails (*Sylvilagus* spp.) can attain speeds of 40 kmh, while the European rabbit has been recorded at 56 kmh (Garland 2009). Home range sizes vary between species, from 0.002 km<sup>2</sup> in the brush rabbit (*S. bachmani*) to 0.140 km<sup>2</sup> in the riverine rabbit (*Bunolagus monticularis*; Table 1). Home range sizes also vary according to sex, habitat quality, and population density. In cottontails, for example, males range further than females – the territory of a single male overlaps those of several females – and home ranges are smaller when population densities are higher as there is increased competition for resources (Chapman and Flux 1990).

Rabbits are generally thought of as being much more gregarious than hares, often occurring in groups and at high densities (e.g., the European rabbit). This is not the rule, however, and population densities can vary considerably showing marked differences within and between species and depending on a wide variety of factors including local climate, habitat, and predator guild composition and relative abundance. The riverine rabbit, one of South Africa’s most endangered mammals with a restricted distribution following widespread habitat destruction, is a largely solitary species which produces very few litters, annually (Table 1). Riverine rabbits also occur at low densities of around 11 individuals per square kilometer (Duthie et al. 1989).

Rabbit social behavior is highly variable, with some species like the European rabbit and the swamp rabbit being highly territorial, while others like the eastern cottontail (*S. floridanus*) are non-territorial. With the exception of the volcano rabbit which emits high-pitched sounds, they are largely nonvocal, alerting others of potential threats by thumping their feet on the ground.

The breeding behavior of rabbits is broadly similar to that of the hares, with males competing for access to receptive females. Both the European rabbit and swamp rabbit display synchronized mating, where matings across the population occur around the same time, resulting in multiple conceptions and an abundance of similarly aged young.

All rabbits give birth to altricial young (kits), which are born naked and with their eyes closed after a gestation period of between 25 and 40 days (e.g., Table 1). However, there is a trade-off between the length of gestation and litter size. Longer gestation results in larger, more developed young which can more ably fend for themselves. However, larger young generally means smaller litters. For example, swamp rabbit kits weigh 56 g when born, after a gestation of 37 days, compared to those of the desert cottontail (*S. audubonii*) which weigh 34 g after a gestation period lasting 28 days. The average litter size of both species is comparable at three kits per litter, but the desert cottontail has more litters per breeding season (five, compared to three for the swamp rabbit; Table 1). Moreover, as with hares and other non-hibernating mammals, the reproductive patterns of rabbits have been observed to vary according to latitude. For example, new world rabbits have shorter gestation periods and produce larger litters in the northern parts of their range when compared to individuals of the same species in the south (Conaway et al. 1974). Such adaptations are a response to latitudinal variations in environmental conditions; breeding seasons are shorter in the north than in the south, and the rabbits maximize their reproductive output, while conditions are favorable (Chapman and Flux 2008).

Old World rabbits actively excavate holes and burrows within which they create a nest of grasses and fur; these offer the vulnerable kits protection from predation and the elements. New world rabbits do not dig, instead utilizing burrows dug by other species, but do create nest holes which are depressions similarly lined with soft vegetation and fur and hidden by a covering of vegetation (e.g., Chapman and Willner 1981). The kits of all species require intensive parental care by the mother (doe) for 2–3 weeks after which they are

fully weaned. Young rabbits attain sexual maturity at around 3 months. Mortality can be extremely high, with as few as 8% of young surviving past their 1st year, depending on several factors including population densities, predator abundance, and disease.

## Pikas

Pikas are a complex of 30 species within a single genus, *Ochotona*, which is itself split into three subgenera: *O. (Pika)*, which is comprised of 8 species; *O. (Ochotona)*, which is comprised of 9 species; and *O. (Conothoa)*, which is comprised of 13 species (ITIS, 2017). Most species of pika occupy cold, remote, mountainous habitats in Asia, Eastern Europe, and North America, though several inhabit open steppe or forest and shrubland. Two species are found in North America, with the remainder found in Asia, particularly China (24 species).

Pikas are smaller than hares and rabbits (70–300 g; Fig. 1; Table 1) and have rounded bodies, rounded ears, and no visible tail. They also differ in skull morphology and dentition (Smith 2008). Adult individuals of the largest species, which include the Chinese red pika (*O. erythrotis*), weigh over 250 g and can reach 30 cm in length. Unlike hares and most rabbits, they are very vocal, communicating via high-pitched calls and whistling barks. They move swiftly in response to a potential threat, taking cover among rocks and/or vegetation, though their hind legs are proportionally shorter than those of other leporids and their gait is very different, being more of a bounce than a hop. Most pikas are diurnal, and they do not hibernate. The average home range of most pika species is small at around 200 m (Table 1). Most species of pika collect caches of vegetation, known as “haypiles,” during the summer which they use as sustenance throughout the winter (Smith 2008). They defend their haypiles vigorously, attempting to ward off potential thieves.

The pikas are split into two major groups: (1) long-lived, territorial species with low reproductive rates which live in rocks or talus, which

includes all North American and half of Asian species and (2) species which generally have short lifespans, high reproductive rates and live in grassland or steppe habitat and are very social (Fontanesi et al. 2016; Smith 2008). There are a few intermediate species which utilize both habitats, adopting the life history traits of the relevant group. Intermediate species include the Afghan pika (*O. rufescens*) and Pallas's pika (*O. pallasii*) (Smith 2008). Pikas are cold-temperature specialists, with high body temperatures; they are sensitive to high ambient temperatures (MacArthur and Wang 1974) and changes in climate (Leach et al. 2015), making them superb indicators of localized warming. This sensitivity means that their distribution is directly associated with climate. While recent studies on American pika (*O. princeps*) have found that they are able to adapt to variations in climate by utilizing favorable microclimates and adjusting their foraging and thermoregulatory behaviors (Beever et al. 2017), pikas are nevertheless generally highly susceptible and likely to experience range contraction to the extent that some species, such as Kozlov's pika (*O. koslowi*), may be driven to extinction (Leach et al. 2015).

There are several differences between the two pika groups. For example, burrowing species such as the steppe pika (*O. pusilla*) have larger litters (around 9 young) and more litters per year (3.5) than rock-dwelling species like the collared pika (*O. collaris*) which gives birth to 2 litters of around 3 young, annually (Table 1). Rock-dwelling species utilize a monogamous mating system, largely due to the dispersal of females across the landscape. Burrowing species also employ monogamy but will also use polygynous, polyandrous, or polygynandrous systems. Both groups are similar – as indeed are all lagomorphs – in that the young are cared for by the absentee mothers; females visit and nurse the young infrequently and for short periods of time. Burrowing pikas are capable of breeding during the summer in which they were born, giving them a higher reproductive capacity than rock-dwelling species which breed in the following year (Smith 1988). There are also differences in population dynamics with rock-dwelling pikas that are largely asocial, occurring at low densities that are generally

stable, year-on-year. Adults vigorously defend territories, though they may be less aggressive toward potential mating partners than other members of the population (Smith and Ivins 1984). In contrast, burrowing pikas are often highly social, utilizing familial burrows; they can occur at high densities (300/ha in plateau pikas, *O. curzoniae*) and their populations exhibit temporal fluctuations. Annual mortality is low in most rock-dwelling species which live for an average of 3–4 years when compared to mammals of comparable size, while mortality is high in burrowing pikas, which also have shorter lifespans (around 2 years) and whose populations have a large yearling cohort (Smith 1988, 2008).

## Definition

Movement of pikas, rabbits, and hares that enable them to move about their environment.

The order Lagomorpha is composed of two extant families: Leporidae (rabbits and hares) and Ochotonidae (pikas). Leporidae consists of 29 rabbit species and 32 hare species. Leporidae typically live in tropical forests, temperate steppes, plateaus, deserts, and Arctic areas (Ge et al. 2013). They are found on all continents except Antarctica and are native to all continents except for Australia and Antarctica (Chapman and Flux 2008; Delaney et al. 2018). Ochotonidae, of which there are 30 species, can be found in North America, Eastern Europe, and Asia. They typically prefer a cold, semiarid, high-altitude environment, and often live in plateau steppe and talus habitats (Chapman and Flux 2008; Delaney et al. 2018).

While lagomorphs can be found in a variety of diverse regions, some species have a narrow habitat tolerance (Chapman and Flux 2008). For instance, the pygmy rabbit requires dense sagebrush, the riverine rabbit is restricted to floodplain vegetation, and the volcano rabbit to zacate grassland (Chapman and Flux 2008). Despite the differences in such habitats, the locomotion in lagomorph species has been adapted for quick movement to escape from predators. Rabbits and pikas generally sprint for cover towards bushes and burrows, while hares are equipped to maintain long distances to outlast predators (Chapman and Flux 2008).

## Gait Sequences

Lagomorphs utilize an asymmetrical gait pattern (Hildebrand 1989). In asymmetrical gaits, the forelimb and hind limb activities are not evenly spaced in time (Granatosky 2018a). The asymmetrical gait occurs close to running speeds which results in decreased contact time between the ground and feet (50% lower than the period of a stride); for a jackrabbit, the contact time between the ground and feet can be as low as 16–18% of the stride. The hind limbs have a longer duration of contact to the ground than forelimbs. This difference in ground contact is also exhibited between the right and left sides (Hildebrand 1989). For instance, the right hind limb may contact the ground for longer than

the left hind limb and vice versa. Within the lagomorph taxa, the pika is the least cursorial followed by the rabbit, with the jackrabbit having the greatest specialization for running (Young et al. 2014).

The preferred mode of asymmetrical gait used by lagomorphs is the half-bound. This gait is seen in animals that use multiple leaps and suspensions with powerful hind legs (Hildebrand 1989). A bound occurs when both hind limbs touch the ground simultaneously followed by both forelimbs. A half-bound occurs if both hind limbs touch the ground simultaneously while the forelimbs are clearly the lead. Both gaits are more conducive for small-to-medium travel spans (Hildebrand 1989). The half-bounding gait of the hare is also useful for “observation leaps,” which aid the animal in avoiding predation by allowing it to better visualize the predator and surrounding area (Bramble 1989). Furthermore, hares are remarkably flexible and can make sudden directional changes as well as rapidly alter their acceleration to flee from predators. Additionally, they can jump to evade predators and can occasionally utilize bipedal locomotion (Williams et al. 2007).

Generally, hares do not exhibit steady-state locomotion. At low speeds, hares saltate (leap); at high speeds, they gallop (Williams et al. 2007). A gallop occurs when there is a lead in both fore and hind pairs of feet. The gallop can either be transverse or rotary. A transverse gallop occurs when both fore and hind leads are on the same side while a rotary gallop occurs when both fore and hind leads are on opposite sides (Hildebrand 1989). Jackrabbits exhibit a rotary gallop. The black-tailed jackrabbit (*L. californicus*) gallop consists of four stages. In the first two stages, the front support on both forelimbs is followed by a suspension stage in which all four limbs are off the ground and are gathered together. In the second gathered suspension stage, the forelimbs are pointed posteriorly while the hind limbs are pointed anteriorly. The third stage is the hind support in which both hind limbs are contacting the ground and are used to thrust into the fourth stage. In the fourth stage, there is an extended suspension with all four limbs off the ground again (Bramble 1989).

## Limb Loading

The hind limbs of lagomorphs work simultaneously to convey a powerful force, allowing the body to move into suspension. The forelimbs are then capable of taking the brunt of the force when they touch the ground from a long leap (Hildebrand 1989). As such, lagomorphs are exposed to frequent abrupt loading on the forelimbs due to their bounding gait (Bramble 1989). As with most terrestrial tetrapods (Granatosky et al. 2018b), the hind limbs function to provide thrust while the forelimbs serve a stabilizing and deceleration role (Williams et al. 2007).

Robust musculature within the proximal hind limb of the hare allows for increased power production and acceleration, which may additionally support the saltation of the hare (Williams et al. 2007). Distal limb muscles of the hare have been shown to produce high force compared to those in the proximal limb. Particularly, the *m. flexor digitorum superficialis* (involved in digital flexion) and the medial and lateral *m. gastrocnemii* (involved in ankle extension) generate the highest force (Williams et al. 2007). The longer fascicles of the proximal limb musculature compared to the shorter fascicles of the distal limb musculature illustrate this difference in specialization. The distal limb muscles also have longer tendons, which reduce the mass of the distal limb and provide a supply of elastic strain energy. Furthermore, abduction/adduction musculature provides stability in the event of sudden turns or change in directionality (Williams et al. 2007).

The forelimbs function as brakes when coming down from a vertical plunge (Bramble 1989). The duration of forelimb-assisted braking is approximately 48–56% of the duration devoted to reacceleration back up into suspension (Bramble 1989). Wild antelope jackrabbits (*L. alleni*) observation leaps have been recorded to produce loads on the body greater than 15 gravitational force equivalent (G) (Bramble 1989). *Lepus californicus* maintains a peak load of 3.5G when its forelimbs contact the terrain in a fast gallop and loads of 9–12G after observation leaps (Bramble 1989). However, the gravitational force is likely greater as these numbers do not consider rough

grounds or spontaneous turns used in natural environments (Bramble 1989).

## Locomotor Kinematics

The kinematic movement of lagomorphs, specifically pikas, is divided into three parts: forelimb movement, spine movement, and hind limb movement. Forelimb protraction and retraction are executed mainly by scapular displacement. Retraction of the scapula begins from the most flexed position at 35–40° in the late swing phase. The mean touchdown angle of the scapula is 46° and mean scapular lift-off angle is 80°. The humerus is almost horizontal at a mean angle of –1° and is held there until the first quarter of the swing phase. The motion of the forearm is mostly parallel to the movement of the scapula especially during the stance phase. The mean touchdown angle of the pika is 33° for the forearm. Forearm retraction continues through the end of stance phase and ends after the start (10%) of swing phase. The mean lift-off angle in the forearm of pikas is 96°. Mean hand touchdown angle is 14°. Hand retraction starts in the second half of the stance phase and ends in the first third of the swing phase. Scapular retraction accounts for 66% of step length in pikas predominating forelimb movement.

For knee and ankle joints, one flexion and extension, a biphasic angular movement per each stance and swing phase is observed. However, in hip joints, a monophasic behavior is shown at asymmetrical gaits. This means that extension enters a plateau during the beginning of stance in pikas. Maximum extension of the hip is reached before lift-off of the trailing limb. Maximum angular extension of the hip joint ends at lift-off in leading limbs. The knee joint flexes before touchdown and reaches maximum flexion at mid-stance when the foot passes underneath the hip joint. Flexion of the knee joint starts earlier in trailing limbs compared to leading limbs (Fischer et al. 2002).

Numerous studies have shown that sagittal bending movements have a major impact on mammalian locomotion and that asymmetrical

gaits are the most efficient mode of locomotion (Schilling and Hackert 2006). Velocity is increased with increased step length via the integration of a long aerial phase and extended stance and swing phases. Cineradiography has been used to assess the intervertebral joint movement in pikas, showing movement from the level of T14/15 to the pelvis. Due to the lack of a tail extending past the contour of the pika's body, individuals show a nearly vertical touchdown ( $100\text{--}111^\circ$ ) and more protracted lift-off position of the pelvis ( $131\text{--}151^\circ$ ). This results in a relatively higher contribution to step length compared to other small therian species with tails that display a horizontal touchdown and retracted pelvis during lift-off (Schilling and Hackert 2006).

### Locomotor and Respiratory Coupling

Lagomorph locomotion has served as the model system to understand the relationship between ventilation and locomotion. Currently, there are three hypotheses on the relationship between ventilation and locomotion. The visceral piston (VP) hypothesis, proposed by Bramble and Carrier (1983) and Bramble (1989), states that during galloping the relative motion of the visceral mass may influence the respiratory cycle. It is thought that upon landing, the cranial motion of the visceral mass, especially the liver, which is attached to the diaphragm, facilitates expiration by decreasing the thoracic volume. Likewise, during the forelimb flight phase, caudal motion of the visceral mass facilitates inspiration by expanding the thoracic volume (Simons 1999). Hence, with each stride, inertial movements of the visceral mass drive cranial and caudal movements of the diaphragm, ultimately inducing expiratory and inspiratory airflows. This concept was further modeled and analyzed by Alexander (1989) in wallabies. In the wallaby, with the deceleration of landing, the viscera moved forward, enhancing expiration. Likewise, with forward and upward acceleration, the viscera moved caudally, enhancing inspiration (Boggs 2002).

According to Young et al. (1992), the vibration mechanics during galloping suggest otherwise.

The vibration mechanics (VM) hypothesis proposes that displacement of the liver is unlikely to drive ventilation. It states that the liver should oscillate nearly  $180^\circ$  out of phase if inertial forces alone were responsible for the motion of the liver. This hypothesis supports the idea of a simultaneous rearward motion of the liver during expiration (Simons 1999).

Simons (1996) argues that the timing of respiration and locomotion is best explained by a pneumatic stabilization (PS) hypothesis, which states that the lungs serve as an important role in the stabilization of the thorax during locomotion. The simultaneous exhalation and forelimb support results in positive pressure in the pleural cavity, which ultimately drives the visceral mass caudally, providing mechanical stability for the heart and other organs (Simons 1999). Boggs (2002) describes this idea as inflated lungs acting like "air-bags," protecting the heart from the full impact of force exerted from the ground.

Analyses of cineradiographic and pneumotachographic data obtained from *Oryctolagus* support the PS model. Since the lungs are intimately associated with the chest walls and are positively pressurized during landing, they may provide mechanical support to the viscera during running (Simons 1996). The results of another study by Simons (1999) confirms that the motion of the liver moves caudally during expiration and cranially during inspiration, supporting the pneumatic stabilization and vibration mechanic hypotheses (Simons 1999).

Running and breathing in mammals report consistent 1:1 locomotor-respiratory coupling (LRC) during galloping (Bramble and Carrier 1983). Since rabbits utilize an asymmetrical gait, the half-bound, they are expected to have a LRC ratio of 1:1. According to Simons (1999), the occurrence of 1:1 LRC increases at higher speeds and stride frequencies, despite the fact that rabbits exhibit a variability in LRC (Simons 1999).

Among most mammals, increased consistency of 1:1 LRC is observed in more cursorial species. Additionally, there are shared anatomical features of cursorial species that noncursorial species lack (Simons 1999). For instance, Ochotonidae is considered to be a more primitive family that is

composed of noncursorial species (Gambaryan 1974), whereas hares (*Lepus*) consist of specialized runners, combining speed, endurance, and agility (Howell 1965; Gambaryan 1974; Bramble 1989). Hares are shown to have unique anatomical variances such as a relatively large heart and lung mass, well-defined grooves in the lung tissue, tissue of the right cranial pulmonary lobe between the heart and sternum, and strong pericardial attachment to the sternum. The *Oryctolagus* and *Ochotona*, both noncursorial species, lack most of these features entirely (Simons 1996). This supports the idea that various anatomical parts within the thorax work in unison during locomotion.

## Opportunity for Bioinspiration

Learning more about Lagomorpha locomotion potentially has a wide range of applications. For example, gaining a better understanding of the biomechanics of the Lagomorpha knee joint may further elucidate the effects of mechanical loading on bone, which can ultimately lead to osteoarthritis (OA) or fractures (Gushue et al. 2005). Specifically, understanding the tibiofemoral joint contact load distribution may be used in theoretical and experimental studies of the rabbit hind limb to draw comparisons to the human knee and further the advancements of OA or fracture treatment (Gushue et al. 2005). Furthermore, studying the gaits of the Lagomorpha may spur advancements in robotics. Pikas, for instance, exhibit the Raibert “self-stabilizing mechanics” with nominal use of neuronal or computational effort while retaining energy (Hackert et al. 2006). Further studies of this phenomena can result in novel applications of Lagomorpha locomotion to robotics.

## Conclusion

Lagomorpha species are terrestrial animals, with considerable variation in their habitat preferences. Ochotonidae (pikas) live in plateau steppe and talus habitats, whereas Leporidae (rabbits and

hares) live in forest, temperate steppe, plateau, desert, and Arctic areas (Ge et al. 2013). The lagomorphs are united by their use asymmetrical, half-bounding gait with interspersed observation leaps. These cursorial and saltatorial adaptations have evolved to promote quick escape from predators. This either involves increased speed in rabbits and pikas or endurance as seen in the hares. Moreover, the hind limbs of the Lagomorpha provide a powerful support to thrust into suspension while the forelimbs absorb the brunt of the force when landing. Lagomorph locomotion has also been used as the model system for understanding how locomotion and respiration are coupled. Finally, studying the Lagomorph locomotion has a plethora of applications. Precise knowledge about their biomechanics may spur robotic innovation as well as medical innovation.

## Definition

Navigation – the theory and practice of charting a course to a remote goal (Schöne 1984).

## Introduction

The daily movements of animals are governed by many factors including the need to find food, water, conspecifics, and favorable environmental conditions while trying to avoid predators, dominant ecological competitors, and unfavorable habitats and conditions. Animals use external cues such as odor (Gagliardo 2013), landmarks (Baader 1996), day length (Baoping et al. 2009), the position of the stars (Dacke et al. 2013), and the Earth's magnetic field (Chernetsov et al. 2017) to guide their movements in the landscape and the timing thereof.

The order Lagomorpha is comprised of two families, the hares and rabbits (Leporidae or leporids) and the pikas (Ochotonidae). The navigational capabilities of lagomorphs are poorly understood, with the few movement studies to have been conducted focusing on dispersal, home range behavior, foraging, and habitat use. Indeed, movement behavior has been entirely unstudied in most lagomorph species. Studying the navigational capabilities of small-to-medium-sized mammals can be challenging as the equipment required for fine-scale data collection (e.g., GPS collars) are often too heavy and/or have limited battery life. For example, the maximum weight for GPS collars is defined by the size of the subject. This is known as the “5% rule” (Cochran 1980); the weight of the collar should not exceed 5% of the focal animal's mass. For a very large hare weighing 5 kg, that would equate to a GPS collar weighing 250 g. The typical battery life for such a collar is around 500 days, though that is based on the recording of only a handful of “fixes” (i.e., records of the individual's location) per day – not enough for nuanced analysis of movement behavior such as navigational strategies (Handcock et al. 2009). The frequency of fixes required for such studies would exhaust the battery in only a few days. However, technological

advances such as the use of micro-GPS and snapshot receivers (McMahon et al. 2017), as well as increasingly lightweight collars and improved batteries, mean that many obstacles are slowly being overcome. It is likely that future technological improvements and dedicated research will lead to a greater understanding of movement behavior and navigational strategies, particularly in larger lagomorphs.

Given the lack of navigation-specific literature, here I broadly summarize research on movement behavior, particularly in the context of home ranges, habitat use, and dispersal, in each group of lagomorphs.

## Hares

Hares (genus *Lepus*; 32 species) are crepuscular/nocturnal open-habitat specialists with long hind legs which allow them to flee from potential predators at high speeds. They are poorly adapted for a digging and rest during that day in above ground depressions, known as forms. As they are not reliant on burrows for shelter and protection, hares generally range over much wider areas than most rabbits and certainly all pikas (see ► “[Lagomorpha Life History](#),” Table 1). However, all hares and their offspring (“leverets”) make use of emergent vegetation for concealment. For example, the Irish hare (*L. timidus hibernicus*), a subspecies of the mountain hare (*L. timidus*), favors open-field habitats (Dingerkus and Montgomery 2002) but is also associated with rough grassland which offers potential cover in the form of stands of rushes (*Juncus* sp.; Caravaggi et al. 2015). Similarly, woolly hares (*L. oiostolus*) favor montane grasslands for foraging but require intermediate shrub habitats for cover (Lu 2011). Researchers studying movements of translocated European hares (*L. europaeus*) found that, rather than establishing home ranges at release sites, the translocated individuals moved to find better habitats which were more similar to those from which they had been removed (Ferretti et al. 2010). Hares will also recurrently use a network of paths between foraging and/or resting sites (Caravaggi et al. 2016).

Dispersal, i.e., the movement of young out of the natal range (natal dispersal) or the movement

of adults to another breeding area (breeding dispersal), is an important process with a key role in population dynamics. The benefits conferred by individuals moving within and between populations and into previously uncolonized habitats are such that dispersal is considered to underpin the persistence of many species (Avril et al. 2011). The causes of dispersal are poorly understood, though it is likely that inbreeding avoidance, mate competition, resource availability, and the density of conspecifics all play a role. The availability of cover vegetation may be a particularly important factor in determining the eventual settlement locations of dispersing females (Avril et al. 2011). Dispersal is ubiquitous and common among hares, though breeding dispersal occurs at lower frequencies than natal dispersal. Moreover, the proportion of young which disperse from the natal range, and the distances travelled, varies between and within species. However, movement behavior during dispersal can give clues to navigational capabilities. For example, dispersing leverets have been observed to use direct long-distance exploratory movements over 1 km before returning to the same resting location, over several days (Reid and Harrison 2010). This return behavior suggests a capacity for accurate navigation on a landscape scale.

The locomotor activity of hares often varies seasonally, with an increase in activity particularly around the start of the breeding season. During this time, individuals will move from their home ranges in search of mating opportunities. It is possible, perhaps even likely, that olfaction plays a role in the location of mates, though olfactory communication in hares is currently not a research priority. Locomotion may also be affected by perceived predation risk (i.e., lunar illumination) and local predator density and abundance (Rogowitz 1997); hares spend more time moving between habitat patches, reducing stationary foraging time in each patch.

## Rabbits

There are ten genera of rabbits (*Brachylagus*, *Bunolagus*, *Capolagus*, *Nesolagus*, *Oryctolagus*, *Pentalagus*, *Poelagus*, *Pronolagus*, *Romerolagus*, *Sylvilagus*), with a total of 29 species. Rabbits differ

physically from hares in that they have comparatively shorter hind legs and shorter ears and are physically smaller (► [Lagomorpha Life History](#), Table 1). Old World rabbits (all genera except for *Sylvilagus*) are diggers, creating underground holes, burrows, and communal warrens in which to rest, avoid threats (e.g., predation, poor weather), and raise their young (known as kits or kittens). In contrast, new world rabbits (*Sylvilagus* sp.) will either utilize holes or burrows dug by other species or raise their young in aboveground forms. The movement behavior of rabbits is poorly understood, with substantial knowledge gaps in all aspects.

Rabbits choose their home ranges with reference to the vegetative composition of the landscape, preferring areas with an abundance of vegetation which could be used for cover. For example, researchers in Spain found that the warrens of European rabbits (*O. cuniculus*) were strongly associated with the *Retama monosperma*, a dense flowering bush (Dellafiore et al. 2008). Rabbits make use of cover vegetation to provide shelter and concealment, often using the same paths through ostensibly safe habitats to reach foraging areas in their home ranges. European rabbits also live in underground warrens which may span a considerable area and have multiple entrances. Within their home range, therefore, European rabbits have a number of options which offer safety from potential threats. Flight to places of concealment is usually direct, suggesting that the animal is aware of its position relative to relevant landscape features.

The proportion of dispersing juveniles is often high, particularly in low-density populations, and, as with many mammal species, dispersing cohorts are often male-biased. However, levels of dispersal may be similar between the sexes when populations occur at high densities (Richardson et al. 2002). In many species, dispersing subadults barely venture beyond their natal home range; males are often more likely than females to make long-distance movements. For example, one male marsh rabbit (*S. palustris*) was recorded as having dispersed over 2 km from its place of birth, compared to most females which did not leave their natal ranges (Forys and Humphrey 1996). In contrast, a study of pygmy rabbits (*Brachylagus*

*idahoensis*) found that females dispersed up to three times further than males (Estes-Zumpf and Rachlow 2009). Dispersal distance may be related to population density (e.g., European rabbit) (Richardson et al. 2002), with long-distance movements being more common in low-density populations.

### Pikas

There are 30 species of pika, all of which are classified within a single genus, *Ochotona*. Pikas are the smallest of the lagomorphs (► [Lagomorpha Life History](#), Table 1), with rounded bodies and ears and no visible tail. Pikas are broadly split into two groups: (i) rock- or talus-dwelling species and (ii) species of grassland or steppe habitats. The two groups have different social behaviors, though they do not differ in life history or ecology. As with other leporids, there is little information available on their movement behavior and navigational capabilities.

Steppe and grassland pikas are social, living in often high-density groups. In contrast, talus pikas are largely solitary and highly territorial. Nevertheless, the dispersal behavior of the two groups is similar. For example, both breeding and natal dispersal distances of plateau pika (*O. curzoniae*; a steppe species) and American pika (*O. princeps*; a talus-dwelling species) are often extremely short, rarely extending beyond two family ranges (Dobson et al. 1998). However, genetic analyses suggested that American pikas may occasionally disperse up to 2 km from their natal range and that intermediate movements may be common (Peacock 1997). Juvenile males are often the primary dispersers in plateau pikas, a pattern not observed in American pika.

The (re)colonization potential of pikas has been shown to be strongly influenced by the degree of habitat patch connectivity, as well as patch quality (Franken and Hik 2004). However, while juveniles are more likely colonize neighboring patches in fragmented habitats, dispersal rates are not necessarily compromised, with a mixture of short- and long-distance dispersal events resulting in a genetically contiguous metapopulation (Peacock and Smith 1997). Thus, dispersing pikas likely use similar exploratory

behaviors to those found in other lagomorphs, facilitated by emergent vegetation and landscape features (e.g., rocks). Researchers investigating the social behavior of the northern pika (*O. hyperborean*) have shown that the species exhibits spatial awareness and recall, with individuals recurrently returning to the same shelter and breeding pairs using multiple collective food caches (Gilwicz et al. 2005).

### Conclusion

Navigational abilities are common features among animals. All lagomorphs exhibit behaviors which can be interpreted in terms of navigational skills, including foraging behavior and the utilization of burrows and/or vegetation for cover. Therefore, it is reasonable to assume that lagomorphs have long-term awareness and understanding of the composition of the habitats and microenvironments found within their home ranges. These cognitive maps (i.e., representations of an animal's environment which are used in decision-making; Tolman 1948) allow them to effectively navigate between foraging and resting areas within their home ranges and beyond such as when making exploratory forays beyond the natal range. However, navigation and movement behavior are understudied in lagomorphs, and, hence, data are scarce. There is scope to expand research in spatial cognition, e.g., mental mapping, into lagomorphs, thus giving researchers greater insight into population dynamics and habitat utilization and requirements, as well as potentially benefitting conservation and management processes.

## Landmark

Marcia L. Spetch

Department of Psychology, University of Alberta,  
Edmonton, AB, Canada

### Definition

The term “landmark” has numerous meanings even within the spatial domain: it can refer to a prominent object that allows one to determine where they are or which direction they are facing (a mountain that is west of a home range), an object used as a beacon (a tree that bears fruit within), or an object that aids in finding another place in a process referred to as piloting (“40 m south of the statue”). These meanings are functional definitions, referring to ways in which an object can guide spatial behavior, rather than properties of the object itself: a landmark can be large like the skyline of a city or small like a rock on the ground. These various functions of spatial landmarks have been studied in numerous species ranging from invertebrates to humans.

### Introduction

Whether an animal uses a cue or which cue an animal uses to guide spatial behavior cannot be determined by observation alone. For example, an ant that suddenly veers to the left may be navigating with the help of visual cues, turning based on motor memory or pheromone trails, or avoiding an obstacle or danger on the right. Identifying whether a particular cue is used as a landmark requires experimental manipulation; typically, the presumed cue is changed in some way to see if it alters behavior, referred to as the transformational approach (Cheng and Spetch 1998).

Most of the research summarized here will concern how landmarks are used to guide search toward a specific location (i.e., piloting). Piloting is generally considered to be a complex process because it cannot be accomplished by a simple approach mechanism but instead involves learning spatial information about the direction and/or the distance between landmark(s) and the goal.

### Classic Studies of Landmark Use

#### Tinbergen’s Wasps

Tinbergen (1972) performed a classic test of landmark use in the field in solitary digger wasps. These insects lay their eggs in nests dug into the ground. During foraging flights, they exit and enter through an inconspicuous hole. To determine whether the wasps use nearby visual cues to find their nest upon returning with food, Tinbergen placed a ring of pinecones around the nest, while the wasp was inside. He then displaced the ring of pinecones to one side of the nest, while the wasp was away foraging. Upon returning, the wasp searched for the nest entrance within the ring of pinecones rather than at the actual nest, clearly indicating the use of the visual cues to guide search to the nest entrance.

#### Rats in a Water Maze

A classic laboratory study of landmark use was conducted in rats using the now-famous water maze task (Morris 1981). The task involves placing rats in a tub of milky water containing a hidden platform that the rat can climb on to escape from the water. Visual cues are provided to help the rat learn where the platform is. If the cues are located at the platform, they can be used as beacons to head toward. If they are located outside of the maze or at a location in the maze but distant from the platform, they can be used to guide search to the platform by learning the direction and/or distance from the cues (i.e., piloting). Studies have shown that these functions are distinct, with piloting by proximal or distal landmarks relying on different brain regions than beaconing to a cue at the goal (e.g., Save and Poucet 2000).

## Piloting by Landmarks

Piloting by visual landmarks has now been experimentally demonstrated in a wide variety of animals, ranging from invertebrates to humans. In an example of experimental research on landmark-based piloting, Cheng (e.g., 1988; see Cheng and Spetch 1998 for review) gave pigeons the task of finding a goal (bit of food hidden under sawdust) in a rectangular search arena. A visual landmark, consisting of a stripe on the wall or an object in the tray, was located at a fixed distance and direction from the hidden food. Over trials, the pigeon learned to accurately find the food, and tests in which the location of the landmark was shifted indicated that the birds used the landmark. Use of this cue was more subtle, however, than simply following exactly the distance and direction specified by the landmark. For example, if the goal was located near one of the edges of the enclosure, the pigeons shifted their search in the direction parallel to the edge in response to landmark shifts, but not in the direction perpendicular to the edge. In addition, shifts of searching were rarely the full distance of the landmark shift, indicating that information from the landmark was used in conjunction with other cues, resulting in a compromise. These general results were replicated in a study with chickadees (*Poecile atricapillus*; Cheng and Sherry 1992) and were also found in a study conducted on a touch-screen computer monitor with pigeons (Spetch et al. 1992). These touch-screen tasks differed from the navigational tasks in numerous ways (e.g., smaller scale of space, graphic landmarks instead of objects, top-down view, pecking instead of moving through space); the similar use of landmarks in these very different tasks suggests that these studies tapped central processes underlying how landmarks guide spatial behavior, rather than task-specific behaviors. Moreover, the partial shifts of searching in the direction of the shifted landmark indicate that multiple cues guided search behavior.

### When and Which Landmarks to Use

Although piloting by visual landmarks is prevalent in a wide range of organisms, there are species differences in the extent to which spatial behavior

is guided by landmarks and the type of landmarks that are used. These differences can reflect many factors, most notably differences in sensory mechanisms and in environmental or ecological adaptations. Studies with ants illustrate both of these factors. Ants have a number of mechanisms for finding their way back to their nest after a bout of foraging; these can include chemical signals from pheromone trails, path integration mechanisms for keeping track of distance and direction traveled, learning of familiar routes, or guidance by landmarks (e.g., Cheng et al. 2009). Habitat seems to influence the relative extent to which ants rely on path integration or guidance by visual cues, with more reliance on path integration for ants living in barren habitats that have few salient landmarks than for ants living in cluttered environments with many visual cues that could guide search (Cheng et al. 2009). The importance of sensory mechanisms was suggested by a study on ants in which the researchers attempted to train the ants to use a large colored cue as a landmark to guide their exit from an enclosure (Legge et al. 2010). The ants ignored this seemingly obvious landmark (to the human eye) but can use skyline panorama, which fits well with the nature of the ant's visual system (Graham and Cheng 2009).

### Using Multiple Landmarks

Using multiple cues to find a goal makes adaptive sense for many reasons. First, redundancy allows for a backup in case one of the cues becomes unavailable (e.g., because of weather-related changes in visibility). Second, use of multiple cues may provide more precise localization of a goal (Kamil et al. 2001) because the bearings from each landmark are subject to error that increases with distance and each additional bearing can be of help to reduce the error. This "multiple-bearing hypothesis" has been supported in studies with Clark's nutcrackers (*Nucifraga columbiana*; Kamil et al. 2001) and humans (Forloines et al. 2015). Third, using multiple landmarks can increase the certainty or confidence that the location is correct. Studies have indicated that humans (e.g., Du et al. 2017) and nonhumans (e.g., Legge et al. 2016) integrate information from landmarks

by weighting the cues according to their reliability or the certainty with which they indicate the goal location. This is consistent with evidence that organisms will integrate information from different types of cues, such as path integration and visual memory (Wystrach et al. 2015) or celestial and terrestrial cues (Legge et al. 2015), often in a Bayesian fashion (see Cheng et al. 2007).

### Competition Between Landmarks

Although information from multiple landmarks is often combined, there are also cases in which the presence of one landmark competes, or interferes, with learning of another landmark. Failure to learn about a new cue when it occurs together with already learned cues is referred to as “blocking,” a well-established finding in the domain of associative learning. Such blocking sometimes also occurs between discrete landmarks in spatial learning tasks (honeybees *Apis mellifera*, Cheng and Spetch 2001; rats, Stahlman and Blaisdell 2009). Even when learning about the location of a goal for the first time, competition can also occur because of differences in the salience or usefulness of cues. This kind of competition, which also occurs frequently in associative learning, is called “overshadowing.” Several studies have found that landmarks nearer to a goal can overshadow learning of landmarks farther from the goal (e.g., pigeons, Leising et al. 2011; Spetch 1995; Clark’s nutcrackers, Goodyear and Kamil 2004).

### Landmark Arrays: Absolute Versus Relational Learning

Consider a situation in which you encounter a patch of wild strawberries when you are out walking, and you want to remember where it is so that you can return to it later. The patch is approximately equal distance in different directions from four nearby spruce trees. You might encode these trees as an array of landmarks and remember that the strawberries are in the middle of the landmark array – an example of relational learning. Or instead you could encode the trees as individual landmarks and encode the direction and absolute distance from one or more of these landmarks. To test whether relational or absolute information is used, experimentally provided landmarks can be

shifted after the learning phase, for example, by expanding the distance between them, to see whether search occurs at the relational location (e.g., in the middle of an expanded array) or at an absolute location (e.g., the learned vector from individual landmarks).

Which type of encoding animals display seems to depend on several factors. One factor is whether the animal needs to use the landmarks to figure out which direction is which. If the animal is already oriented within the search space (as would be the case if you knew your heading direction when you were walking or if a pigeon searches in a space containing salient directional cues such as a door on one side of the room), then the landmarks may be used for goal localization but are not needed to get bearings. In this case, many species seem most likely to use absolute information, learning the distance and direction from one or more of the individual landmarks, rather than searching at the relational location (e.g., Collett et al. 1986; Mac Donald et al. 2004; see Kelly and Spetch 2012 for a review). Pigeons do this both with arrays of graphic stimuli on a touch-screen monitor and with real objects in an open space, suggesting that this absolute spatial encoding is not task-specific (Spetch et al. 1997). This result contrasts strongly with adult humans, who almost always respond based on the relational rule (Spetch et al. 1997). On the other hand, if distal directional cues are blocked, animals show relational encoding of the landmark array (Sturz and Katz 2009). Moreover, birds can use landmark configuration to distinguish between different landmark arrays (Sutton 2002), and they can encode relational information from an array of landmarks if training precludes the use of absolute information (e.g., by varying the distance between the landmarks in training; Kamil and Jones 1997; compare to Kelly et al. 2008). These results suggest that animals show considerable flexibility in how landmarks are used and they illustrate the distinction between what animals typically encode from a landmark array and what they can encode. The effects of training also suggest a possible reason why adult humans typically show relational learning of landmark arrays: our extensive experience with scale transformations

of space from pictures and maps may predispose us to prioritize relational information. Interestingly, honeybees also seem to respond to relational information from arrays of landmarks, searching farther from an array of landmarks when the distance between them is experimentally increased (Cartwright and Collett 1983). In this case, the reason appears to be because the bees use a view-matching process in which they search at a location that best matches the remembered image of the landmarks from the goal. Finally, rats in water mazes appear to learn the confirmation of landmarks to find the platform (Benhamou and Poucet 1998), perhaps because they use these cues for orientation as well as goal localization.

### How Landmarks Are Used to Guide Search

There is ample evidence that many animals can extract both distance and direction information about a goal location from discrete landmarks. It is less clear exactly how the information is extracted. Some studies have suggested that bees (Cheng 1998) and birds (Cheng 1994; Pritchard et al. 2015) independently encode distance and direction information, whereas at least one study with rats suggested that whole vectors from landmarks were encoded (Gibson and McGowan 2014).

### Conclusions

Using visual landmarks to pilot to a goal is widespread among animals and is one of several navigational mechanisms that allow animals to find their way around and return to important places such as home or sources of food. Accurate and efficient navigation is often crucial to survival, so it is unsurprising that animals show flexible and often sophisticated mechanism for selecting among or integrating information from cues to guide spatial behavior.

## What Is Communication?

Communication is the process through which one individual transmits information to another. This

process involves some form of behavior, such as the production of a signal that is generated by one individual that acts as a sender and is transmitted to another individual that acts as a receiver. When a receiver is present to perceive the sender's signal and process the associated information, communication is said to have occurred. Others have clarified this distinction as, "Communication does not begin when someone makes a sign, but when someone interprets another's behavior as a sign" (Knight et al. 2000). In many forms of communication, the sender can then transmit another signal in response, and thus both individuals take on both roles in the course of communicating. The information from a sender can be transmitted in many different ways. For example, the information can be as simple as one organism being seen by another and thus revealing its location. That same information can also be conveyed through other modalities, such as listening to the sounds that a distant organism produces and determining its location in that way. These are very simple examples of information being transmitted, but exchanged information can also be much more complex, as is the case of the detailed information contained in a recipe for chocolate cake or the nuanced information conveyed in a friend's warm smile and cheerful tone of voice.

One of the most familiar forms of communication that humans use is language. Language is an especially efficient means of communicating complicated ideas quickly and effectively, and it is a powerful tool to help people describe their ideas, express their emotions, and understand the thoughts and feelings of others. Language involves the use of sounds or written symbols, and these constitute a lexicon through which a sender imparts information to a receiver. This is often done by taking turns, such as alternation of speaking during a conversation or an exchange of texts or emails, and individuals who are fluent in a given language use those sounds and symbols equally well as either sender or receiver. The ability to use those relatively few sounds and symbols in specific arrangements to convey an amazing diversity of complex ideas is thought to be a defining characteristic of human cognition (Prather et al. 2017). In the following sections, we will discuss spoken and written language as a means of communication, the influence that

language has had in humans' emergence as the dominant species on our planet, the cells and circuits through which the nervous system enables communication through language, and the ways in which those insights relate to our understanding of how humans communicate in ways other than spoken or written language.

## What Is a Language?

Despite being such a prominent feature of our everyday experience, language can be challenging to define. Some researchers have defined it as "a system of arbitrary vocal symbols by means of which a social group cooperates" (reviewed in Cyelan 2017). This definition captures language as an entity that is communicated through speech, but it leaves unaddressed the ways that we communicate using written language, as in the case of this text, or manual gestures, as in the case of signed languages. Others have described language as the ability to communicate, as both sender and receiver, using a specific and shared set of symbols such as sounds or written letters (reviewed in Cyelan 2017). This much broader definition is consistent with what many people mean when they use the term language, but it also leaves open questions about how different a set of symbols must be in order to identify them as different from those of another language. For example, even among people who are fluent in the same language, no two people speak in exactly the same way. These individual idiosyncrasies do not impede the process of communication, so those two people would be described as each speaking the same language. If we look beyond individual speakers, we can sometimes encounter much greater differences in pronunciation or terminology, and these are often distributed across different geographical regions. These localized differences are called dialects of the language, as their differences are clearly detectable, but they do not hinder an individual's performance as either sender or receiver, and therefore they do not impede the process of communication. These examples highlight that there can be variation in how the symbols that comprise a language are produced by different individuals. There is no

single definition of how much variation is required to establish a boundary between different languages, but it is clear that successful communication is the primary requirement in considering whether symbols constitute different languages. In that light, a useful functional definition of language is a set of symbols through which senders and receivers can exchange information, express ideas and emotions, and influence the thoughts and activities of others who share the same set of symbols.

In communication through the use of language, information can be transmitted through vocal gestures, as occurs in spoken conversations, or through written symbols or other forms of manual gestures, as occurs when we write or type letters such as those you are reading now. These types of complex vocal and manual gestures are inherent to how we communicate using language, but complex behaviors alone are not sufficient to say that language is being used. For example, many animals use vocalization as an important form of communication, such as the roar of a lion or the songs and calls of a bird. Those vocalizations are key elements of how those species communicate, but they are typically used to communicate relatively simple information such as territoriality or aggressive intent (Catchpole and Slater 2008). In other species such as chimpanzees, individuals modify their use of vocalizations in different social contexts such as different calls in association with food sources of different sizes (reviewed in Cheney and Seyfarth 2018), but even those vocalizations are lacking a key feature that defines communication through use of human language. That feature is the rules-based organization of symbols into combinations through which complex information can be transmitted. These have been referred to as the “design features of language” and more recently as the “faculty of language,” and they include things like the ability to structure words in such a way that they refer to abstract ideas or objects that are not physically present, or they clarify that the sender is describing the past or the future, or they provide the sender with the ability to use language to talk about language just as we are doing here (Hauser et al. 2002; Pinker and Jackendoff 2005;

Wacewicz and Zywickzynski 2015). Through the symbols and organizational rules of language such as recursion, fluent speakers can assemble a finite set of symbols into different combinations to reliably communicate an infinite set of facts, thoughts, and emotions. Thus, a central aspect of the beauty and importance of language lives in the ability to create the infinite from the finite. By applying the rules of linguistic structure, future plans can be made, and the consequences of possible actions can be considered. Objects can be referenced and described even if they are unfamiliar because they existed far away or long ago or even if they may have never existed at all.

No set of behaviors with as much complexity and communicative power as human language has ever been described in other species. Some aspects of those communicative advantages are present in the behaviors of other species, such as a bird’s identity being detectable from the traits of the songs that it sings or a bird’s ability to produce strings of sounds with patterning that has led some to speculate that it constitutes a form of syntax (Catchpole and Slater 2008; Gentner et al. 2006). However, none of those vocalizations appears to have anything approximating the descriptive and referential power of the sounds that we use in language, and no set of animal behaviors incorporates all of the traits that define human language. Interestingly, bees appear to be able to use their complex “waggle dance” behaviors to communicate about the location and quality of food sources (Price and Gruter 2015). This has led to speculation about the intellectual capacity of bees and whether their movements related to food may meet some of the criteria to call those behaviors a rudimentary form of language. Although elaborate and useful to communicate specific information, those behaviors appear to be restricted such that they are used only to refer to food sources and relevant navigational information to find those sources. In contrast, humans are unrestricted in what we can describe using language. In some cases, training or other forms of relevant experience may be necessary to communicate about abstract ideas or new discoveries, but that can be readily achieved by fluent speakers, and the ability to learn and achieve such expansion highlights

the power of language as a tool to link current status to almost unlimited future possibilities.

A key feature of communication through language is that both the sender and the receiver must use the same set of symbols. This highlights the role that learning plays in acquiring those symbols and developing fluency in a language. As detailed in a later section, the ability to communicate using language is an imitative form of learning. Factual content appears to be learned intentionally, such as the fact that a canine pet is called a “dog” in English, but the fact that we learn language at all appears to emerge from a natural predisposition to interpret the noises made by others as meaningful signals (Pinker and Jackendoff 2005). Language is typically acquired during very early life, with nascent speakers learning the sounds that comprise their native tongue by listening to the sounds produced by others around them (reviewed in Prather et al. 2017). Humans are extraordinarily skilled in our ability to hear the detailed features of sounds used in language, as evident in the features of different regional accents often shared by children and the parents from whom those children learned their language. This link between sounds that are heard and sounds that are produced relies heavily on the sense of hearing, with a healthy sense of hearing being essential for young speakers to learn those sounds and refine their imitation of those model behaviors (reviewed in Prather et al. 2017). This is most clearly evident in people who are deaf or experience other forms of hearing impairment. People who are deaf from birth have great difficulty acquiring and refining the sounds used in spoken language. Even among people who achieve complete fluency prior to any hearing impairment, their clarity of spoken language is typically reduced if their hearing impairment is severe or prolonged. Other animals such as parrots and songbirds are also very skilled at imitating the sounds they hear produced by others, and these species are even capable of expressing regionally distinct features that are sometimes described as dialects. Yet despite the complexity of their songs and their skill in imitative learning, there is no evidence that birds are capable of using their vocalizations to refer to a range of different ideas

or otherwise communicate with the complexity and productivity of human language. Together, these examples from the animal kingdom serve to highlight the extraordinary utility of human language. In fact, the ability to communicate so broadly and so effectively through language appears to be uniquely human.

## Written Language and Its Role in Human History

Writing enables thoughts and emotions that are expressed in language to persist through time, and it enables the accumulation of information far beyond the knowledge of any single individual. Through translating thoughts into a system of symbols, thoughts can last far longer than a single utterance or even a single lifetime. Those symbols can represent entire words, as in the characters used in Chinese, Japanese, Korean, and Vietnamese writing, or they can represent consonant and vowel sounds arranged in a specific sequence, as in the letters of the English language that are used here. This latter form of written representation constitutes an alphabet, and the individual letters represent the basic sounds of language (Bright and Daniels 1996). The first use of an alphabet to represent linguistic sounds is thought to have occurred among the Phoenicians, and those written symbols were used as a tool for communication in trade throughout the Mediterranean area (Bright and Daniels 1996). That system is thought to have influenced the development of the Greek alphabet, as the Greeks adapted the Phoenician writing system to represent the sounds they used in their own language (Bright and Daniels 1996). The Greeks built on the Phoenician writing system to create a system with individual symbols that represented both consonants and vowels and that could be arranged in a linear sequence to communicate information. For this reason, some people consider the Greek writing system to be the first true alphabet (Bright and Daniels 1996). Others further adapted the Greek system for their own needs, such as the Latin script that was an ancestor of the 26 letters that compose the English alphabet (Bright and Daniels 1996).

Alphabets were transformative because they enabled people to archive their thoughts. Prior to that, the ideas and traditions that compose a people's culture were passed from one generation to the next orally. Writing enabled those stories to be collected and placed into reservoirs that could be preserved and consulted anew by members of subsequent generations. These reservoirs, which we call "books" in English, were originally made from thin bits of material taken from the bark of trees. The Latin word for that material (*librum*) gave rise to the terms *liber* to refer to what we would call a book and *librarium* to refer to a place where books were collected and stored. In its earliest days, creating books was a very laborious task, with scripts written by hand onto sheets of fragile material that were very challenging to store and preserve. It could take a very long time to create even a single book, and it was even more challenging to create multiple copies. Thus, books were a means of archiving information if they were stored very carefully and protected from catastrophic events such as the fire that engulfed the Library at Alexandria in 48 BCE, but books were still not practical as a means of disseminating that archived information.

A key advance in our collective ability to archive and share information broadly came in the year 1493 when German inventor Johannes Gutenberg invented the printing press. Modeled on the wine and olive presses of that time, Gutenberg's means of pressing paper onto movable type could produce finished sheets much more quickly than the speed at which texts could be copied by hand. This was vastly more efficient, and it enabled more rapid production of texts that could be shared among many readers. Advances in the ability to communicate have continued to emerge, and they now enable nearly instantaneous communication through electronic tools such as phones, texts, and emails. These advances have increased the speed and breadth of dissemination, but in their essence they all rely on language as the means through which communication is possible.

Language has given humans an amazing ability to describe and disseminate our ideas. With the assemblage of those ideas into culture and technological advances, language has been a key

feature in driving our collective history. Through spoken and written language, humans have communicated across space and time. That accumulated knowledge allows us to benefit from intellectual masterpieces produced by earlier thinkers, such as Plato's *Republic* and Newton's *Philosophiae Naturalis Principia Mathematica*. It allows us to revel in gripping stories, such as the *Epic of Gilgamesh* and the works of Shakespeare. It allows us to learn from the insights of others, such as Aesop's *Fables* and China's *Shangshu*. It allows us to share sacred texts, such as the *Torah* and the *Koran*, and it has allowed us to learn from historical documents, such as the *Sumerian Code* and the *Magna Carta*, as we continue to refine the policies that shape our governments and social structure. Through these examples and countless others in our collective history, communication through language has shaped our conceptualization of technological and cultural wonders and our advancement as a species.

## Acquisition of Spoken Language

Ideas can be communicated and archived through written communication, but they can be brought alive through forms of behavioral emphasis such as changes in vocal pitch and emphasis that are expressed through intonation. Many concepts can be equally well conveyed through written or spoken language, but in some cases additional aspects of meaning can be communicated in speech that are difficult or impossible to express in written language. Just as punctuation plays a key role in written communication, intonation can play a key role in illustrating a person's meaning in speech, such as the rising intonation that occurs during the final words of a person asking a question in English. These prosodic elements can also clarify a person's complete meaning in words that might otherwise be easily misunderstood, such as occurs in emphasis, contrast, irony, or sarcasm (Purves et al. 2001).

The properties of speech can be described using parameters such as rhythm, articulation, and voice. Rhythm refers to the temporal organization and the sense of movement in speech,

evident in the timing and stressed nature of some syllables, as well as the number of syllables in each word (Gleason and Ratner 2016). For example, in the English language, unstressed syllables are spoken more quickly than stressed syllables, acting as an indicator of the focus of a message. Also inherent to rhythm are brief epochs of silence, with very short pauses used to separate words, slightly longer pauses used to separate phrases much as commas do in text, and longer pauses used to provide emphasis or to illustrate breaks between complete thoughts, acting in the same way that periods or paragraphs break written language into meaningful chunks. Articulation refers to the precise movements of the structures involved in actually producing the sounds used in speech, such as the lips and tongue (Gleason and Ratner 2016). Strictly speaking, these are elements of vocal production and therefore speech rather than aspects of the conceptualization that characterizes language. However, articulation is an integral part of producing spoken language, and disorders of that ability can complicate a person's ability to communicate. Voice (sometimes called "vocalization") refers to how we use our vocal folds and breath to create the sounds used in speech (Gleason and Ratner 2016). Voice is also used in ways other than speech. For example, voice serves as an auditory identifier such that we can recognize different individuals by hearing their voice even if other identifiers such as their face are not visible. Voice can also indicate emotional state, and these features can be detected even by newborn babies (Missana et al. 2017). Together, these features of vocal production and behavioral emphasis give rise to the rich and complex signal that is spoken language.

Spoken and written languages share the feature that symbols are used to represent specific thoughts. For example, either reading the word "dog" or hearing it spoken by your friend could equally well produce a mental image of a cute furry pet. As we noted earlier, information is communicated in written languages through symbols such as characters or letters. Those symbols can be combined to represent thoughts, and those thoughts can be communicated in their full rich entirety. In spoken language, the relevant building

block of meaning is called a phoneme. Phonemes are perceptually distinct units of sounds that distinguish one word from another (Gleason and Ratner 2016). As you listen carefully to spoken words, phonemes are the smallest unit of each word that provides specific meaning. For example, "cat" and "bat" are very similar in the middle and final portion of those words, but they are very different in their first sounds. The difference between those sounds is typically very easy for listeners to distinguish, and that facilitates a listener's easy identification of those words and rapid realization of their meaning. Phonemes are produced with specific temporal patterns that allow the speaker to be understood by the listener. These rules that govern the structure of sentences in a language are collectively called syntax (Gleason and Ratner 2016). When a speaker fails to adhere to the syntax of a language, the listener may misinterpret or be unable to interpret the message being conveyed. When the many traits of a language such as rhythm, voice, and syntax, come together to enable rapid and efficient communication, a person has achieved fluency in that language (Gleason and Ratner 2016).

Fluency in a language is a learned behavior that we acquire by imitating other speakers of that language. Typically, language develops at a very young age, beginning at around 6–9 months of age (Gleason and Ratner 2016). Those first steps toward linguistic ability are often characterized by vocalizations that are difficult to recognize and consist of a series of sounds that is devoid of linguistic meaning. That stage of development is called babbling, and it is thought to be associated with young speakers developing their vocal control, preparing them to be able to repeat common words they hear and recognize the associations with those words (Gleason and Ratner 2016). This process of gradually learning to produce the phonemes that define meaning in spoken language and to bind informational content to specific sounds is the beginning of vocabulary and semantics (Gleason and Ratner 2016). As the young speaker continues to develop, they typically make grammatical or other errors of syntax, and these are usually corrected through experience or instruction from others. When these

vocal, semantic, and syntactical features of spoken language improve in concert, the young speaker is on their way to fluency of spoken language. That skill in spoken language then becomes the basis for subsequent acquisition of written language. Fluency emerges as the young person becomes progressively more skilled at communicating in both realms.

When the process of language development is successful, the individual acquires fluency as both sender and receiver, and communication can occur easily and reliably. However, difficulties in communication can emerge if either sender or receiver experiences challenges such as difficulty perceiving sounds, trouble producing sounds, difficulty with rhythm and continuity such as stuttering, challenges with voice control such as dysphonia, or other challenges that impair production or comprehension. These difficulties can cause communication to be slowed or complicated or to fail completely. Creating solutions to those challenges through the development of mechanistically targeted therapies will require an understanding of the neural mechanisms that are affected in each type of disorder. That desire to improve the lives of the many people impacted by those conditions has been the driving force behind over a century of research into how we learn, perceive, and perform the sounds we use in spoken language.

## Language and the Brain

The link between language and specific areas of the brain first emerged through studies that investigated speech deficits and corresponding injuries to specific regions of the brain. In 1840, a French patient named Louis Victor Leborgne was admitted to a Paris hospital with symptoms that included being able to utter only one syllable (Domanski 2013). That syllable was “tan,” and even though Mr. Leborgne could inflect his voice and he often accompanied that syllable with various expressive gestures, he could not speak any additional content. Whatever had happened to induce this state had left him with an impaired ability to communicate that was far from the

fluency that he had previously enjoyed. Dr. Pierre Paul Broca had an opportunity to treat Mr. Leborgne. Dr. Broca specialized in the study of language, and he found it very curious that a patient could suffer such a loss in one realm but be apparently unaffected in other faculties. Dr. Broca carefully documented this loss of the ability to speak in Mr. Leborgne and other patients, and in papers published in the 1860s he described a condition that we now call expressive aphasia or Broca’s aphasia. When Mr. Leborgne died, it was discovered that he had a large lesion in a specific area of his brain. That area, the posterior inferior frontal gyrus in the left hemisphere of the brain (specifically the pars opercularis and pars triangularis, also described as Brodmann’s areas 44 and 45), is now commonly referred to as Broca’s area (Dronkers et al. 2007). This link between the sudden emergence of nonfluent speech and a corresponding brain injury was the first hint that a specific brain site could play such an important role in language.

In the years following Broca’s discoveries, others also became interested in the possibility that injuries in other sites could also be related to the emergence of other types of language difficulties. In 1874, Dr. Carl Wernicke described another type of aphasia in which patients had fluent speech in which they could produce many different words, but those words were disordered to such a degree that it was difficult or impossible to understand the patient’s meaning (Purves et al. 2001). His patients also commonly had difficulty understanding speech, and this was evident as impairment of their ability to follow directions or to repeat a sentence that they had just heard. This form of impairment is now called receptive aphasia or Wernicke’s aphasia. After the patients expressing receptive aphasia died, it was discovered that their linguistic deficits were also associated with injury to a specific brain site, but in these cases the injuries were at a different site than reported for Broca’s patients. These patients with receptive aphasia had damage in a region near the interface of the temporal and parietal lobes in the left hemisphere of the brain, in a region including the posterior portion of the superior temporal gyrus and other sites that are collectively called

Wernicke's area (Mesulam et al. 2015). This led Wernicke and others to propose that specific regions of the brain may be specialized to shape different aspects of behavior and that the full range of behaviors emerged through the interaction of those and other sites. Additional studies have also found other areas of the brain that are closely associated with other aspects of behavior, such as other areas near the classically defined Wernicke's area that also influence speech comprehension, and visual regions that contribute to how we recognize faces (Binder 2017; Cohen et al. 2019), but these early studies by Wernicke and Broca provided the first insights into the neural sites and pathways that play key roles in language (Hagoort 2019; Scott 2019; Tremblay and Dick 2016).

The fact that Broca's and Wernicke's areas both resided in the left hemisphere of the brain suggested that linguistic function could be lateralized such that it resides primarily or exclusively in the left hemisphere. Subsequent studies confirmed that there can be differences between functions associated with corresponding areas of the left versus the right hemisphere, but they have also revealed that language is affected to at least some degree by both hemispheres (reviewed in Taylor and Regard 2003). This is called hemispheric dominance, and in most people the left hemisphere is dominant for language (reviewed in Prather et al. 2017). The left hemisphere appears to play the dominant role in articulatory ability, such as being able to form meaningful sequences to respond to questions, but areas of the right hemisphere corresponding to Broca's and Wernicke's areas in the left hemisphere also contribute to subtle features of understanding that accompany linguistic ability. For example, patients with injury to those regions of the right hemisphere can lose the prosodic elements of language, such as intonation, stress on certain syllables, and the rhythm of speech production. Patients with injury to the right hemisphere can also have difficulty with word-association tasks, suggesting that the right hemisphere may help us to bind meaning to specific words, even if it is not directly driving articulation of those words. These patients can also have difficulty categorizing

things or understanding metaphors, drawing inferences, or grasping the non-literal meaning of idioms used in speech (e.g., "it's raining cats and dogs," Taylor and Regard 2003). Thus, the left hemisphere plays a dominant role in the production and comprehension of language in most people, but both hemispheres contribute to the full richness of communication.

The quest to continue expanding our understanding of the neural basis of language drives much current research. Central to that effort are studies of learning, as learning to imitate the sounds we hear perform by others is a central component in our acquisition of language. In its essence, that learning process consists of auditory perception instructing motor performance. When that process proceeds to accurate completion, imitation emerges. That is especially evident in the regional accents that humans express, such as the gentle lilt of accents from certain regions of the American South. If parents and others in the region speak with such an accent and their children model their vocal development on the sounds that they hear throughout development, then the children are very likely to imitate with sufficient precision that they also speak with that accent. Accents and other examples make it clear that the human brain is capable of very precise imitation in the acquisition and performance of language, but it remains unknown how the brain enables perception to inform motor performance.

Specialized brain regions in other species offer us a chance to gain high-resolution insight into mechanisms of imitative vocal learning. For example, songbirds acquire their songs by imitating the sounds they hear performed around them during their juvenile development (reviewed in Catchpole and Slater 2008). Although those songs are not used in the same way that we employ our language, they are learned, rehearsed, and performed in a way that is strikingly similar to how we acquire speech (Catchpole and Slater 2008). Songbirds also have specialized neural circuits that underlie that process, and those circuits are analogous to circuits in the human brain (reviewed in Prather et al. 2017). Therefore, studies of the cells and mechanisms through which songbirds learn to perform their songs may also

inform our understanding of the imitative process through which we acquire the sounds we use in speech.

A study performed using sparrows revealed cells in which activity is closely related to auditory perception. Those cells are very selective in their auditory responses, with robust responses to one song in the bird's vocal repertoire (Prather et al. 2008, 2009). Those cells are thus among the most selectively responsive sensory neurons ever described. Different cells are responsive to different song types such that the entire vocal repertoire is represented in the population of these cortical neurons (Prather et al. 2008, 2009). Closer examination of the song that is capable of driving a response in each cell reveals that there are highly detailed song features, such as a combination of two notes produced rapidly in a sequence, that are the salient features in driving the auditory response of the cells that are tuned to that song type (Prather et al. 2008). Behavioral studies combined with experimental alteration of the parameters of that salient feature revealed that the cells are not active in association with the specific parameters such as note duration. Instead, the cells are active in association with the bird's perception of the note (Prather et al. 2009). Those highly selective cells are typically unresponsive to the songs of other birds, but if that salient feature is present in the song of another bird, then they respond (Prather et al. 2008). Thus, each of these cells is selectively responsive to an element of the sounds these birds use in communication.

A breakthrough in our understanding of the possible link between perception and production came when researchers recorded from the same cells described above as the bird performed the salient song feature. They discovered that those cells were as selective in the motor domain as they were in the auditory domain, with each cell being active in association with one song type in the bird's vocal repertoire (Prather et al. 2008). The key finding was that these cells were active in association with the same song type in each domain, so that each cell was active in association with both perception and production of one and the same vocal behavior (Prather et al. 2008). Each of these cells was active in association with

one learned vocal behavior, regardless of whether that behavior was perceived through the ears or performed through the voice. This colocalized representation of both perception and performance in these cells earned them the name "mirror neurons" (reviewed in Prather et al. 2008, 2017). Because each of these cells is a site where there is a link between perception and performance, they are ideally suited to serve as a mechanism linking those behaviors in imitative learning. Many authors have speculated that this sort of link between perception and performance also underlies human acquisition of language (Lieberman et al. 1967). The discovery of such a mechanism in songbirds provides researchers a context in which to explore the properties of one such link. Discoveries that continue to emerge from studies of neural mechanisms in songbirds will help guide exploration and understanding of corresponding mechanisms in humans, opening the door to development of new mechanistically targeted therapies to ameliorate the challenges of impaired human communication.

### **Communication in Ways Other than Spoken or Written Language**

For some people, such as those who are deaf or otherwise hearing impaired, communication through spoken or written language can be very challenging. In those cases, other forms of linguistic communication are necessary. Languages that incorporate visual-manual communication to convey meaning are known as signed languages. These are complete, natural languages, possessing their own lexicon and grammatical systems in addition to other aspects that are also present in other forms of language (Sandler and Lillo-Marton 2006). Signed languages use a combination of manual articulations to produce the content of a sentence, and they use non-manual elements to convey grammatical function. The patterns of vocal stress and intonation that are used to enhance meaning in a language may not be possible in these contexts, but those forms of prosody are preserved in signed languages through non-manual elements, such as body posture or the

movement of the head, eyebrows, eyes, and mouth. Through the use of non-manual elements such as facial expressions, the speaker can indicate emotional content, such as whether they're making a statement, asking a question, adding emphasis, or being sarcastic (Liddell 2003).

Signed languages are distinctly separate from other visual-manual communication systems such as “baby sign language” and signs learned by non-human primates. In baby sign language, parents teach hearing babies a small set of signs to facilitate clear and effective communication between parent and baby. This type of signed communication is a form of symbolic support for the development of spoken language rather than the development of a language itself (Fitzpatrick et al. 2014). Humans sometimes teach non-human primates signs to allow them to facilitate communication between those primates and their human caretakers. These cases indicate that non-human primates are capable of forging links between symbols and meaning and thus communicating through signs, but their development of that skill fails to progress into the full grammatical complexity that is characteristic of a complete signed language (Wallman 1992). Thus, although babies and non-human primates can learn to express themselves through signs, they have not been shown to develop their knowledge of a human language as a complete system.

Signed languages should not be confused with body language, though they may appear similar. Body language is a form of non-verbal communication that uses physical behaviors, such as facial expressions, posture, eye contact, and gestures to express emotion or convey information (Pease and Pease 2004). Unlike signed languages, body language lacks a grammar system and can be broadly interpreted, rather than have specific meanings that correspond with specific movements or gestures. As a result, body language is not considered a language in the lexical and grammatical sense, but is central to how we communicate emotional content, and we colloquially refer to it as a language because of its prevalence and its importance in social communication (Waciewicz and Żywiecziński 2010). Culture has a strong influence on how body language is perceived.

For example, greeting someone with a firm handshake can have a different connotation in one culture compared to another. A firm handshake in Western culture is perceived as confident, whereas, in Eastern culture, it is perceived as aggressive (Black 2010). Other gestures can mean the difference between praise and insult, such as giving a thumbs up. In American and European cultures, a thumbs up is a sign of a job well done or understanding; however, in some Middle Eastern cultures, that same gesture would be interpreted as dismissive and a form of insult (Black 2010). Depending on the cultural context in which they are expressed, a range of different behaviors including eye contact, sitting position, and silence can hold an entirely different meaning (Pease and Pease 2004). In contrast, the semantic properties of individual words in a language are much more constant across a similarly wide range of contexts.

Another means through which humans communicate, especially about our emotional status, is music. Similar to language, music has a hierarchical structure that can be broken down into the smallest relevant units of sound, with those units being phonemes in language and individual notes in music (McMullen and Saffran 2004). As in the case of languages, music has “rules,” or a sort of “grammar,” to govern the logic of how individual notes can be used (Mehr et al. 2019; Patel 2008). Notes can be combined into sequences or chords that coalesce to create melodic and harmonic lines of a song. In music, the melody is the main focus of a song, and it serves as a means of communication between composer and audience. A rich variety of information, such as emotional context, can be implied through various aspects of the melody, and harmonies can serve as an additional supporting framework for the melody. In that way, the emotional content and story inherent in the melody can be made richer and fuller by the addition of harmonies into a piece that might otherwise sound hollow and fail to achieve its emotional impact. Through this rich acoustic content, music possesses affect and is thus capable of stirring emotion and conveying meaning.

Because of the prevalence and ability of music to convey emotion across human cultures that

speak many different languages, some authors have referred to music as a “universal language” (Longfellow 1835). Studies seeking to investigate that possibility have revealed that certain features of music, such as pitch or tempo, can be used by listeners of many different cultures to accurately interpret whether a song is about a specific emotion such as love or sadness (Mehr et al. 2019). Those studies also revealed that tonality, referring to the organization of musical pieces around a central note and the relationships between notes and chords that can be used to build or resolve tension, is also widespread (Mehr et al. 2019). These findings point to music as ubiquitous and influential across a range of diverse cultures and musical types, consistent with the idea that it might play some role as a universal form of communication. Experts, however, caution against the colloquial usage of the term “language” to describe music as compared to how it is used to describe spoken and written communication (Jackendoff 2009). For example, the quality and beauty of a piece of music can be quite different for members of different cultures, especially for those that reside in cultures where the tonal content of their local musical style is quite different from that of the piece of music that is played for them (Patel 2008). In that light, the role of music as an artistic means of conveying emotion appears to be broadly conserved across humans, but its role as a means of providing enjoyment appears to be more culturally based rather than holding a universal status.

### **Language as a Dynamic Entity Central to Culture**

Language is central to human culture, providing a means through which humans are able to express ideas, emotions, and needs. The development and use of language is ubiquitous in human history, as evident in the fact that much of history itself is archived through the use of language. A review of our collective history makes it clear that languages have changed as they have evolved over time, as different cultures have come into contact with one

another, and as we have adapted to new needs and opportunities in communication. For example, humans have developed tools to encode languages in ways that help to increase inclusivity and overcome distances that separate people. One such tool is Braille, which is a tactile writing system of raised dots that can be read with the fingers by those who are visually impaired (Sadato 2005). Braille itself is not a language, but rather a code for language to be written and read. It transforms a previously established alphabet into representative shapes and bumps, with no new grammar or vocabulary. Thus, Braille conveys information through a new representation of already-established letters and words, and therefore it is considered a tool of communication rather than a language all to itself. Similarly, Morse code is a method that encodes text characters as a sequence of dots and dashes (Coe 2003). Codes are transmitted as electrical pulses of varying lengths, often detected as pulses of sound or visual cues such as light flashes. Morse code provided a means of communication that can cross vast distances, eventually giving way to other tools such as the radio, telephone, and television that are so familiar today. As is the case with Braille, Morse code is a change in representation, facilitating communication through already-established languages rather than the emergence of a new language.

History also reveals changes in the prevalence and properties of languages as different cultures have come into contact with one another (Lee 2020). For example, a pidgin is a grammatically simplified means of communication that develops between groups who encounter one another but do not have a shared common language (Lee 2020). The pidgin that emerges from that interaction can serve as a bridge for communication among native speakers of different languages. In some cases, pidgins are then passed onto the next generation of speakers and become a formalized native language with fully developed grammatical and syntactical systems. When a pidgin language has been transformed from a communication bridge to a full-fledged language, it is known as a creole language (Lee 2020). In contrast to pidgins,

creoles have a consistent system of grammar, large stable vocabularies, and are learned by children as their native language, distinguishing them as languages rather than just blends of other languages.

In other instances of interaction between speakers of different languages, their languages have changed more drastically, sometimes becoming either endangered or extinct. Today, there are approximately 7,000 languages in use (Anderson 2012). Some of those languages are experiencing challenges to their prevalence because of younger generations not acquiring them, or because they are spoken by small and dwindling numbers of people, or because they are being used in only certain circumstances, such as family use, but not others, such as commercial use (Lee 2018). These languages are considered to be endangered (Lee 2018). Among these endangered languages are Irish Gaelic, Hawaiian, Louisiana Creole, Zenaga, Bih, many Native American languages, and many other languages spoken in various regions around the world (Eberhard et al. 2020). Their endangered status means that they are vulnerable to loss as a tool of communication and a central element of their associated cultures. In addition to having relatively few current speakers, some of these languages are especially vulnerable to loss because they are primarily or exclusively spoken languages that are not written down and thus have no dictionary, literature, or historical record.

Outside influences such as globalization can contribute to the loss of local languages, as global influence and the demands of commerce can lead members of those cultures to adopt languages that are spoken more broadly. Some languages are spoken so broadly as either a native or a second language that they are considered “world languages.” These include languages that are commonly used in trade and international relations, such as English and French (Eberhard et al. 2020). If speakers of local languages transition to speaking primarily or exclusively those world languages, that can result in local languages being further threatened or perhaps even going extinct, with other languages taking over the role of that

lost language in the local culture. If those languages fade away in their usage, cultures can lose an important facet of their identity. In response to such concerns, groups seeking to preserve cultural history have collected recordings of those speakers and examples of their literature to help preserve the cultural identity of the associated group. Through those efforts, it is hoped that cultural treasures can be preserved that would otherwise be lost as the language in which they are composed becomes increasingly more threatened.

Languages are ever-evolving, living entities that are still changing today. With the emergence of new social trends, language can grow through the introduction and wide incorporation of new slang words. As these words become integrated into wide use, they can eventually be added as formal additions to the dictionaries that define that language. Thus, the vibrant social trends that a language enables are also the engine that can drive its change. This is especially evident in some of the words that have moved from slang to inclusion in canonical dictionaries. For example, the English word “ain’t” is a contraction with many possible usages and meanings, including “am not,” “are not,” “is not,” “have not,” or “has not.” For many years, use of the word “ain’t” was considered incorrect and was discouraged for use beyond casual conversation. This was despite the fact that “ain’t” first appeared in dictionaries in the 1830s. More recently, words like “hangry,” which is a portmanteau of “hungry” and “angry” that describes the feeling of irritability due to hunger, and “vacay,” meaning a form of vacation holiday, have also been added to the dictionary. These examples and many others make it clear that languages are living entities that will continue to grow and adapt as they both drive and respond to changes in human cultures.

## Introduction

Historically, one of the cognitive hallmarks ascribed to humans has been the ability to communicate using language. Language is a multifaceted and complex ability that allows us to assign arbitrary symbols meaning and to use and understand these symbols in referential exchanges with others that draw joint attention to agents, objects, and events both present and displaced in space and time (Nelson 1977; Savage-Rumbaugh 1986). Language also allows us to employ rules called syntax to generate different combinations of symbols that extend meaning beyond the individual symbol, and allows the same symbols in different combinations to create completely different meanings (Bronowski and Beluggi 1970; Savage-Rumbaugh et al. 1993). Neurobiology, cognition, and the acoustic and social environments to which we are exposed at an early age all have a profound influence on the initial language or languages we acquire (Hoff 2014). Yet even as adults our linguistic abilities are cognitively pliable allowing us to learn new languages involving symbols and syntax that are different from our so-called mother tongue. While the requisites for language development are still debated, there is no disagreement that language is a powerful tool that allows humans to negotiate interactions within large, complex long-term social networks. Yet we are not a unique species in having large social networks of this type, and it is this shared feature with humans along with a relatively large brain, cognitive abilities including imitation that rival many nonhuman primates, a protracted period of maternal care giving, and naturally learned vocal labels associated with individuals (Marino et al. 2007), that has inspired

researchers to investigate language abilities in bottlenose dolphins (*Tursiops truncatus*). Below, I review this research focusing first on studies exploring the referential function of naturally developed signature whistles, and then on studies using artificial systems to investigate the dolphin's ability to acquire two key aspects of language, semantics and syntax.

### **Research on the Referring Function of Dolphin Signature Whistles**

Bottlenose dolphins develop novel individually unique whistle contours termed "signature whistles" (Sayigh et al. 2007). These specialized whistles become part of a dolphin's vocal repertoire and can function to announce personal identity. Although signature whistles have been studied since the 1960s (Caldwell and Caldwell 1965), several findings over the last 20 years have provided evidence that these whistles can be used in referential communication. Individual signature whistles are developed when dolphins are young through vocal learning in which calls heard in their environment are modified to create a frequency modulated pattern that is used instead of voicing characteristics to acoustically encode a dolphin's identity (Janik et al. 2006). The production of signature whistles in captivity when one dolphin from a group voluntarily isolates itself, or the exchange of signature whistles between individuals in the wild before joining other groups, suggests that these whistles can be used to maintain cohesion between group members (Janik and Slater 1998). In addition to the majority of a dolphin's whistle repertoire being its own signature whistle, it may also imitate the signature whistles of close associates (Tyack 1986), and distinguish the whistles of family members from other familiar individuals (Sayigh et al. 1999). The question of whether signature whistles for dolphins, like names for humans, can have a referring function in addition to broadcasting a dolphin's own identity has intrigued researchers for decades. Janik (2000), using a hydrophone array to localize vocalizing wild dolphins in the Moray Firth, Scotland, found that a dolphin after hearing

the signature whistle of another dolphin out of visual range vocally matched this dolphin's signature whistle within less than a second. Based on these findings, Janik (2000) suggested that bottlenose dolphins might use signature whistles to address each other. More recently, King and Janik (2013) provided compelling evidence that the production of a facsimile of a dolphin's signature whistle can be used to address that individual. During focal follows of dolphins off Scotland, the researchers first recorded a dolphin's signature whistle, then created a synthetic version of that whistle with voice characteristics removed (i.e., in order to model the production of that dolphin's signature whistle by another dolphin), and finally either played back this facsimile or control whistles of either a familiar dolphin from the same population or an unfamiliar dolphin from a different population. Within one minute of the playback, dolphins hearing the facsimile of their own signature whistle responded most often by producing their own version of their signature whistle, a response that rarely occurred with the familiar controls and was absent with the unfamiliar controls. The findings supported the hypothesis that signature whistles can be used and understood in referential exchanges between dolphins. However, thus far there is no evidence of the use of signature whistles in different syntactic forms, and no evidence beyond signature whistles of the natural vocalizations in a dolphin's repertoire being used to refer to objects, locations, or events.

### **Research on the Comprehension of Sentences Within an Artificial Language System**

In the late 1970s Dr. Louis M. Herman, founder and director of the University of Hawaii's Kewalo Basin Marine Mammal Laboratory, launched a series of groundbreaking studies to investigate the ability of bottlenose dolphins to respond accurately to imperative and interrogative sentences given within artificial languages that required processing of both semantic and syntactic components (Herman et al. 1984, 1993a; Herman and

Forestell 1985). Herman chose to focus on sentence comprehension rather than production because of problems encountered by early ape language studies that focused on sentence production. These problems included procedural flaws allowing for nonlinguistic cueing of apes, the often erroneous assumption that an ape's production of a symbol to acquire something implied that it understood this symbol referentially, and that ape productions of strings of signs were often highly redundant, generally failed to extend meaning, and lacked the essential feature of sentences that changes in word order can change meaning (Terrace et al. 1979; Seidenberg and Petitto 1979; Savage-Rumbaugh et al. 1980; Ristau and Robbins 1982). Herman also took into account the finding that in humans, language comprehension tends to precede and exceed production (Bates 1993). Two young female dolphins, Phoenix and Akeakamai (Ake), were trained respectively in an acoustic-based language and a visually based language in which either brief computer-generated sounds projected into the dolphins' pool or individual gestures of a trainer's arms and hands were associated with different agents, objects, actions, modifiers, relationships, and function words. Phoenix's initial vocabulary consisted of 32 symbols and Ake's 30 symbols (Herman 1986). The goal of the study was not to determine how large a vocabulary the dolphins could master, but rather to explore whether object symbols were understood referentially and the extent to which the dolphins could spontaneously understand the different meanings conveyed by many unique combinations of vocabulary items. The set of grammatical rules that governed how symbols could be combined into different orders in each language allowed for the creation of over 2700 sentences up to five words in length.

### The Dolphin's Understanding of Imperative Sentences

Imperative sentences consisted of nonrelational instructions requesting that a named action (A) be performed to a named Direct Object (DO), and relational instructions requesting that a

relationship (R) be created between a DO and an Indirect Object (IO). The dolphins were also taught contrasting symbols that could serve to modify named objects. Phoenix was taught the modifiers SURFACE and BOTTOM (of her pool). Ake was taught the modifiers RIGHT and LEFT (from her perspective when being signed to). During trials, several different pairs of surface and bottom objects or left and right objects were present so that the occurrence of the modifier alone did not by default designate a particular object.

The syntactic rules in each language were identical for nonrelational sentences. Two-word nonrelational sentences took the form DO+A and indicated that the named action should be performed to the named object. For example, BALL+TOSS instructed the dolphin to find a ball from a variety of objects in its pool and toss it with its rostrum. Three-word nonrelational sentences took the form Modifier (M) + DO+A and indicated that the named action should be performed to the modified named object. For example for Phoenix, BOTTOM+PIPE+TAIL-TOUCH instructed her to touch her tail flukes to the pipe lying on the pool floor. For Ake, LEFT+-HOOP+UNDER instructed her to swim under the hoop to her left.

For relational sentences, the syntactic rules were different for each dolphin, but in both cases specified that a DO should be either transported to the side of an IO if R was FETCH or placed in or on top of an IO if R was IN. For Phoenix, the sequence of symbols matched the order in which the sentence was to be carried out, with three-word relational sentences taking the form DO+R + IO. For example, FRISBEE+FETCH +BASKET instructed Phoenix to bring the Frisbee to the basket. For Ake, an inverse syntactic rule was used to construct relational sentences such that the sequence of symbols was not directly correlated with the order in which the sentence was to be carried out. Here, three-word relational sentences took the form IO+DO+R. Thus, to ask Ake to create the same relationship as required of Phoenix above, the trainer would sign BASKET+FRISBEE+FETCH. For both dolphins, relational imperative sentences of four and five words could be created from their respective

three-word relational sentence syntactic forms by adding a modifier prior to one or both object names. Thus, the two four-word sentence forms for Phoenix were M + DO+R + IO and DO+R + M + IO, and for Ake they were M + IO+DO+R and IO+M + DO+R. Likewise, the five-word sentence form for Phoenix was M + DO+R + M + IO and for Ake it was M + IO+M + DO+R. The use of the inverse syntactic rule for relational sentences of three, four, and five words in Ake's language not only tested for dolphin mental flexibility in understanding different syntactic structures, but also examined sentence parsing in which the question of how to treat the initial object symbol of a sentence was conditional on the remaining elements. Thus, when Ake sees the gestural sign BASKET, she must wait for the next gestural sign to know whether basket is to be treated as a DO as in BASKET+SPIT (meaning *spit water at the basket*), or as an IO as in BASKET+BALL+IN meaning *put the ball in the basket*. Regardless of structural differences between Phoenix and Ake's languages, both contained identical conceptual features essential for examining sentence comprehension. First, each semantic element within a sentence whether M, DO, IO, or R could be fulfilled by multiple exemplars within a category. Thus, every word used in a sentence was functional and meaningful. Second, the structure of the relational sentences allowed for the construction of semantically reversible sentences (i.e., sentences in which the same words appeared but in different orders creating changes in sentence meaning). For example, for Ake the same three words appear in the sentences PERSON+SURFBOARD+FETCH and SURFBOARD+PERSON+FETCH. However, the former sentence instructs Ake to transport the surfboard to the person while the latter instructs her to transport the person to the surfboard. For Phoenix, the semantically reversible sentences connoting parallel meanings to those expressed above would be SURFBOARD+FETCH+PERSON and PERSON+FETCH+SURFBOARD.

After the dolphins were taught the sounds or gestures for each of a small set of objects, actions,

and the relationship fetch, as well as how to respond to two-word nonrelational sentences and three-word relational sentences using these symbols, they were tested for comprehension of two types of novel sentences, lexically novel sentences in which new words were placed in one or more syntactic slots of a familiar syntactic form creating semantic propositions the dolphin had never experienced previously, and structurally novel sentences involving the creation of a new syntactic form on which the dolphin had not been trained. Language sessions occurred regularly and employed a variety of controls, including opaque goggles being worn by trainers, to prevent cueing.

### The Dolphins' Responses to Lexically Novel Sentences

Herman (1986) reported that Phoenix and Ake performed wholly correctly, meaning that they interpreted accurately each of the words in a sentence as well as its structure on 67.5% of 191 lexically novel sentences and on 65.4% of 214 lexically novel sentences, respectively. Both performances were well above what would be expected by chance (calculated at 4% or less depending on the sentence type). Furthermore, during tests of the dolphins' responses to all of the various types of nonrelational and relational sentences (both familiar and novel) in the languages, Phoenix responded wholly correctly to 81% of 234 relational sentences and Ake responded wholly correctly to 66% of 128 relational sentences. On those sentences that were semantically reversible Phoenix was correct on 77% of 128 sentences and committed only one error in which she reversed object order and function (i.e., taking the IO to the DO), and Ake was correct on 59% of 69 sentences and never committed a reversal error. Collectively, the dolphins' responses to lexically novel sentences provide compelling evidence that both the meaning of the words (the semantic component) and their arrangement (the syntactic component) were processed accurately. Furthermore, the dolphins

immediately transferred their understanding of symbols to novel exemplars and to novel situations (Herman 1986, 1987). For example, the gesture for hoop was initially taught to Ake using a specific large octagonal hoop. Subsequently, she immediately transferred this gesture to hoops of varying shapes and sizes. Both dolphins also regularly rearranged their environment to make requested actions possible to perform. When given HOOP+THROUGH *meaning swim through the hoop*, and encountering for the first time a hoop lying flat on the bottom, Ake lifted one end of the hoop with her rostrum and darted through. Thus, Ake (as well as Phoenix) understood that object symbols referred to classes of objects rather than to specific exemplars and also understood action symbols conceptually.

### The Dolphin's Responses to Structurally Novel Sentences

Several types of structurally novel sentences were presented to each dolphin including for the first time for Ake, four-word sentences. Although Ake had previously experienced M + DO+A and IO+DO+R sentences, she had never experienced a Modifier within a relational sentence. Nonetheless, the first time she was signed sentences following the syntax M + IO+DO+R and IO+M + DO+R she responded accurately. Phoenix had experienced a modified DO within a relational sentence previously, but not a modified IO. Nonetheless, she responded accurately on the first occasion she experienced a DO+R + M + IO sentence. In addition, Phoenix adapted her responses meaningfully to structurally novel sentences that either linked two action words within a relational sentence or conjoined two non-relational sentences into a single sentence. In the first case, Phoenix was given sentences in which the word FETCH was followed by either the word THROUGH or UNDER or OVER. Prior to this time, she had only experienced FETCH singly in a relational sentence and the words THROUGH (*meaning swim through*), UNDER (*meaning swim under*), and OVER (*meaning jump over*) in non-relational sentences. The first time Phoenix

experienced FRISBEE+FETCH+UNDER+HOOP, she responded accurately by transporting the Frisbee under the hoop. Subsequently, she was wholly correct on 53% of 436 trials of the three types of linked actions within relational sentences. Phoenix was also given 15 trials conjoining two non-relational sentences, for example, PIPE+OVER+PIPE+TOSS to which she first jumped over the pipe and then tossed it with her rostrum. She carried out both named actions to the named object correctly on 11 of the 15 trials including the first time she experienced a sentence conjoining two nonrelational sentences.

### The Dolphin's Responses to Anomalous Sentences

Among the strategies used to investigate what children understand about the grammar they employ is to examine their responses to so-called anomalous sentences (i.e., sentences that either violate a grammatical rule or a semantic relation or substitute "nonsense" words for real words) (e.g., de Villiers and de Villiers 1972; Carr 1979). The assumption is that a child's interpretation of such sentences reflects its understanding of the syntactic rules in its language, the semantic characteristics of words, and the semantic relations between words. Herman et al. (1993a) investigated Ake's responses to both syntactic and semantic novel anomalous sentences. Syntactic anomalous sentences were those containing extended strings of gestures that violated Ake's familiar syntactic language structure. For example, as noted earlier nonmodified relational sentences for Ake took the form IO+DO+R with those objects that she could transport serving as possible DOs and both transportable objects (T) and nontransportable typically stationary objects (S) serving as IOs. Thus, using the terminology of transportable objects and stationary objects, Ake's nonmodified relational sentence form IO+DO+R could be rewritten as (either T or S) + T + R. One syntactic construct that violated this familiar relational form was the sequence S + S + T + R because there is no

syntactic rule that uses a string of three object words followed by a relationship word. Nonetheless, when Ake was presented with such syntactic violations she commonly extracted subsets of words that comprised a “legitimate” grammatical rule. For example, when given the anomalous sentence SPEAKER+WATER+PIPE+IN for the first time, Ake extracted the legitimate sequence SPEAKER+PIPE+IN and placed the pipe on top of the speaker. Ake’s extraction not only conformed to the familiar syntactic rule  $S + T + R$ , but also revealed her composing a meaningful sentence from two nonadjacent object words. This type of solution when faced with a syntactic anomaly occurred not only for the form  $S + S + T + R$  but also for  $S + T + S + R$  and  $S + T + T + R$ . In total, out of 19 four-word anomalous sentences, Ake extracted legitimate sequences of two object words on 14 occasions and was wholly correct, meaning she also performed the correct relational term in 12 cases.

Semantic anomalous sentences were those in which a legitimate syntactic form was followed in constructing a sentence but a semantic rule was violated. For instance, the form  $(T \text{ or } S) + S + R$  is legitimate syntactically (i.e., it contains two object names followed by a relationship term), but asks Ake to transport a nontransportable object (S). For instance, WATER+SPEAKER+IN instructs Ake to put the stationary speaker on top of the stream of water coming from a hose attached to the pool railing. Ake was given 12 novel semantic anomalous sentences of the type  $(T \text{ or } S) + S + R$ . In the majority of cases, Ake rejected the sentence (simply remaining at her station), and in several instances she substituted a transportable object for the designated nontransportable DO, thus composing a sentence that could be performed. Overall, Ake’s responses to anomalous sentences that violated both syntactic and semantic rules revealed that she understood the functional relationship of various grammatical frames to each other, the functional relationship of word positions within these frames, and the functional relationship of different categories of words (i.e., which named objects were transportable and could be substituted legitimately for designated nontransportable objects).

## **The Dolphin’s Responses to Sentences Referring to Objects Displaced in Space and Time**

A key feature of language is the ability to understand linguistic references to arbitrary objects (i.e., those that are not biologically or ecologically meaningful) that are displaced in space and time (Hockett 1960). Such comprehension demonstrates both that the symbols and their referents are represented mentally and that the symbols can act as surrogates for the objects they represent (i.e., the symbols are understood as referencing the objects even in their absence). Herman et al. (1984) carried out studies with both Phoenix and Ake exploring their ability to accurately carry out two-word nonrelational sentences to objects that were displaced in space and time. With their pool empty of objects, a sentence was either signed to Ake or projected to Phoenix. Once the sentence was completed, seven different objects were introduced into the pool from arbitrary locations. The dolphins performed equally well, each correctly carrying out 81% of 43 different two-word sentences. Following this, Ake was tested on the same type of displacement procedure with delays between sentence completion and the introduction of objects into the pool up to 30 seconds. Although there was some degree of memory loss with increasing delay, Ake performed accurately on 53 (88%) of 60 two-word sentences. In other tests in which when the sentence was given the objects were located out of sight in a remote pool that Ake could only access through a narrow channel, she was correct on over 95% of the trials. Collectively, these findings demonstrate that both dolphins could understand references to objects displaced in space and time.

## **The Dolphin’s Responses to Interrogative Sentences About the Presence of Objects in Her Pool**

Herman and Forestell (1985) developed a specific interrogative sentence form to further investigate Ake’s ability to understand semantic references to objects displaced in space and time.

The interrogative sentence form OBJECT NAME+QUESTION asked Ake to report symbolically on whether the named object was currently present in or absent from her pool. To respond to such queries, Ake was provided with a paddle to her right, designated as the “Yes” (i.e., object present) paddle and one to her left, designated as the “No” (i.e., object absent) paddle. Thus, if the trainer signed HOOP+QUESTION and there was hoop in her pool, Ake would press the Yes paddle indicating that the named object was present. Alternatively, with no hoop in her pool, Ake would press the No paddle indicating that the named object was absent. Ake was trained to report presence and absence in response to the OBJECT NAME+QUESTION interrogative sentence with a single named object, the hoop, and then she was tested for transfer of the concept with five named transportable objects from her language (frisbee, pipe, basket, net and ball) all of which she had responded to previously in imperative sentences but which she had never been asked about using the OBJECT NAME+QUESTION interrogative. The five transfer objects allowed 10 novel trials to be conducted, 5 in which the object referred to in the query was present and 5 in which it was absent. During testing sessions, between 1 and 3 objects were shown to Ake and tossed into the pool behind her. The trainer donned opaque goggles and then signed either OBJECT NAME+QUESTION or DO+A. If when given the latter sentence the named object was present, she was correct if she carried it out in her normal fashion. If it was absent, Ake was correct if she pressed the No paddle. Overall, Ake responded correctly on 82% of 324 imperative and interrogative sentences including correctly reporting object presence on 80% of 108 trials and object absence on 77% of 108 trials. She also carried out the correct DO+A sentence on 88% of 108 trials in which the named object was present. A key finding was that Ake reported presence or absence correctly on 9 of the 10 novel transfer trials described earlier. Combined, Ake’s ability to accurately report presence and absence strongly supports the idea that she understood the referring function of gestural symbols for objects in her

language, and that these symbols could act as surrogates for the objects they represented.

### **The Dolphin’s Understanding of References to an Individual Whose Behavior It Should Copy**

Important to any demonstration of referential understanding is that symbols can be understood in different contexts and functions. As shown above, Ake understood the gestural signs for objects in her language in multiple contexts and functions including as direct or indirect objects in imperative sentences and as the subjects of interrogative sentences. The latter strongly demonstrated that Ake understood the referring function of these symbols in that no response to an object was required, only a symbolic report on its state of existence in the pool. This suggests that when the trainer signed an object name, it evoked within Ake a mental representation of that object. A further context within which Ake’s gestural symbols were understood referentially requested her to imitate the motor behaviors of either a person in the pool or the dolphin Phoenix (Herman et al. 1993b). During a 24-trial test with Phoenix and a person simultaneously performing different motor behaviors, Ake responded accurately to the sentences PERSON+-IMITATE and PHOENIX+IMITATE by attending to the behavior performed by the referenced individual (79% correct) and creating either a close approximation or an exact facsimile of that behavior (84%). These high performance levels not only showed that the object symbols were understood in a radically different context from those previously employed but also that they served to manage joint attention, a key feature of referential communication (Savage-Rumbaugh 1986).

### **Research on Artificial Symbol Production**

The success of Herman’s work as described above reveals the importance and fruitfulness of examining receptive language competencies in

dolphins as well as in other animal species (Herman 1987). Nonetheless, given the success of language studies focusing on both comprehension and production in bonobo chimpanzees (*Pan paniscus*) using objects that are functionally different and meaningful (Savage-Rumbaugh 1986; Savage-Rumbaugh et al. 1993), some recent studies with dolphins have attempted to examine symbol production beyond signature whistles. Earlier and prior to the behavioral imitation work with Ake, she was trained to vocally imitate arbitrary computer-generated underwater sounds in response to the sequence AKE + IMITATE+ MODEL SOUND (Richards et al. 1984). Ake was highly proficient in mimicking a variety of model sounds including those sounds novel to her experience. She was also able to mimic some of the sounds used in Phoenix's language to represent objects. Following this, she showed that she could produce facsimiles of these sounds when the physical object associated with the sounds was shown to her. However, there was no evidence of her producing these sounds out of this context to request or comment on the associated object, possibly because most of the language objects were specifically designed to be arbitrary and not functionally meaningful in different ways to the dolphins.

In other work at Marine World Africa in California, Reiss and McCowan (1993) examined the interactions of two young male dolphins with a keyboard on which different visual symbols (keys) appeared in different configurations. When a key was pressed, it resulted in the underwater projection of a computer-generated whistle associated with that key followed by a human either offering the dolphin an object (ball or ring) or an action (rub) associated with that particular key and sound. The dolphins were not trained through operant procedures to press a key to obtain a sound or its associated object or action, but instead were allowed to explore the contingencies of the keyboard on their own. As the dolphins began pressing keys, they also began both mimicking the sounds and producing facsimiles of these sounds. The production of four facsimiles, two for ball and two for ring, on four separate occasions occurred just prior to one of

the males hitting the appropriate associated key. A much larger set of appropriate facsimile productions of whistles for ball, ring, rub and a combination of the separate whistles for ball and ring into a single continuous whistle were recorded in the context of a dolphin being in contact with the object or objects associated with that whistle or whistle combination. This occurred in 80% of 92 ball productions, 73% of 64 ring productions, 100% of 5 rub productions, and 82% of 28 ring-ball combination productions. Although intriguing, these data on symbol production were not sufficient to consider the communication referential.

A later underwater keyboard project conducted with two male dolphins at EPCOT's Living Seas in Walt Disney World, Florida, used humans to demonstrate the contingencies of activating keys on the keyboard in addition to the dolphin's own explorations (Xitco Jr. et al. 2001). The activation of a symbol on the keyboard simultaneously resulted in the projection underwater of the English word associated with the particular food, toy, tool, or location represented by the symbol. During sessions, one or two human SCUBA divers were paired with a dolphin and together searched the habitat for named goal objects in named locations. The goal objects consisted of food, toys, and tools that were typically hidden randomly in the habitat in transparent containers that, for a dolphin, required human assistance to open. Following 6 months of exposure, each dolphin after attending to a human activating a symbol on the keyboard was observed to swim ahead of the human, rather than waiting for him or her, to the correct object or location represented by that symbol and point to the object with its rostrum and aligned body while gazing back and forth between the object or location and the human. Each dolphin also began spontaneously activating the symbols themselves. However, while details were provided on the dolphin's spontaneous pointing behavior, suggesting that it was referential in character (Xitco Jr et al. 2001), not enough detail was provided of the dolphin's symbol production and comprehension to evaluate whether the symbols themselves were understood referentially.

## Conclusions

Our understanding of dolphin language abilities has increased dramatically since the initial descriptions of dolphin signature whistles in the early 1960s (Caldwell and Caldwell 1965). Recent findings on signature whistles of bottlenose dolphins are consistent with the interpretation that these natural learned whistles reflect individual dolphin identity and are used and understood in symbolic referential exchanges between individual dolphins (Sayigh et al. 2007; King and Janik 2013). Laboratory studies by Herman and colleagues have revealed that dolphins can be successfully tutored in artificial languages that contain various linguistic features (Herman and Uyeyama 1999). These studies demonstrate not only that dolphins can understand the referring function of arbitrary sounds or gestures towards objects, even in their absence, but also that they can immediately respond accurately to imperative and interrogative novel sentences that require an accounting of both word meaning and word order (Herman et al. 1984, 1993a, 1993b; Herman 1986, 1987). Other laboratory studies using keyboards in which dolphins are not explicitly taught the meaning of keys but discover this either on their own and/or through observational social learning have provided evidence of the vocal production of different learned whistles associated with desirables in appropriate contexts (Reiss and McCowan 1993), and have led to spontaneous referential pointing by dolphins to direct the attention of human companions towards items they desire (Xitco Jr et al. 2001). Fruitful directions for future studies of dolphin language abilities might examine whether dolphins can understand declarative sentences, can respond to interrogatives beyond questions about object presence, and can produce symbols in multiple contexts that demonstrate an understanding of their referring function.

## Language Research: Great Apes

Alexandria Cairo-Evans  
University of Chicago, Chicago, IL, USA

## Definition

Great ape language research explores how and when mechanisms for language may have evolved and explores the range and dynamics of linguistic capabilities in great apes. This research is concentrated around the mid- to late 1900s and turn of the century and includes a wide variety of studies focused on the induced development of language ability across a variety of modalities, spoken, signed, and visual, in several species of Hominidae: Pongo (orangutan), Gorilla (eastern and western gorilla), and Pan (the common chimpanzee and the bonobo).

## Introduction

Language research is inextricably tied to questions of human uniqueness. For all the different ways in which animals communicate – auditorily, visually, chemically, even electrically – language has evolved only one time. Modern language research is a culmination of the efforts of researchers from diverse fields including linguistics, evolutionary biology, and cognitive, developmental, and comparative psychology. The practice of cross-fostering apes or rearing them in the home environments similar to that of the foster parents' (human) own children, has fallen out of practice, and the ethical and practical considerations coupled with changing interests has led to the conclusion of the bulk of language research with great apes. Subsequently, research has largely diverged into study of primate cognitive ability more generally but consisting of a greater variety of capabilities (working memory, problem solving, metacognition, etc.).

While a thread of criticism and question to the validity of experimental findings (Terrace 2019) runs through much of the research conducted with apes as language users, there is a consistent focus for future researchers on improving language studies of the past. The first nonhuman primate linguistic studies consisted of attempts to teach spoken English, which gave way to signed languages and an emergent visuo-symbolic language using graphic representations. A wide variety of methodology for instruction in language and tests of accurate and effective production have been used in many different ape species, and these primates' abilities have led to studies of other cognitive abilities beyond the development of linguistic ability.

## Spoken Language

### Unnamed Orangutan

There is a longstanding tradition of cross-rearing in the great ape subjects of language research. In one of the earliest investigations into the linguistic

capabilities of nonhuman primates, Furness (1916) reared two orangutans and two chimpanzees largely in his Pennsylvania home. With slow and gradual coaching, one successful orangutan (*Pongo* spp.) was able to produce the word "Papa" appropriately as a proper noun referring to her caretaker, Furness. With manual training and manipulation of the nose and mouth, the unnamed orangutan was able to produce the word "cup," and eventually the "th" sound as a precursor to intended future study of words such as "this," "that," and so forth. When the orangutan died, Furness (1916) employed a similar method in an attempt to teach one of his chimpanzees to produce English nouns as well, but was unsuccessful, coming to the conclusion that orangutans held more promise as conversationalists.

### Gua

Interested in both language and questions of nature versus nurture, Kellogg and Kellogg (1933) co-reared the common chimpanzee (*Pan troglodytes*) Gua, acquired from the Anthropoid Experiment Station of Yale University (which would become the Yerkes Primate Center before its move to Atlanta, Georgia) alongside their infant son, Donald beginning at 7.5 and 9 months, respectively. Aiming to provide an upbringing to both that was as similar as possible, the Kelloggs provided comparative reports on the skill and behavioral development of both Gua and Donald. At 16 months, Gua's testing indicated a comprehension of 58 English words and phrases; at 18.5 months, Donald comprehended 68. Vocalizations were produced by Gua; however, these were affective in nature and never amounted to a spoken word. Several gestures were used by Gua, however, which corresponded with desires such as eating or sleeping. This behavior led Kellogg and Kellogg (1933) to speculate that signed languages may be an avenue for achieving language in apes.

### Viki

Perhaps the most successful verbal English-using ape, at just a few days of age, Viki, a common chimpanzee, was adopted into the home of

Florida-based Yerkes Primate Center researchers Hayes and Hayes (1951, 1952). As some success had been seen in cases of great apes raised in a manner similar to a human child, Viki was also bottle fed, wore diapers, and high importance was placed on a typical infant upbringing, though with a key difference in language tutoring. Viki participated in extensive and rigorous “speech therapy” and vocabulary training. Viki would be one of the last great apes to participate in research focused on production of spoken language, but she achieved production of four words: “Mama,” “Papa,” “up,” and “cup,” as well as other sounds, and demonstrated comprehension of spoken words and phrases directed at her (Hayes and Hayes 1951, 1952).

Teaching Viki to speak was a challenge, and in reflection, Hayes and Nissen (1971) considered the cognitive ability and practical physical limitations of a chimpanzee. Drawing comparisons to American Sign Language (ASL), evidence from Viki’s successes and shortcomings indicated future studies may benefit from using signs or gestures as opposed to spoken words.

## Signed Language

### Washoe

At their home in Reno, Nevada, RA Gardner and Gardner (1969) were already using ASL with Washoe, a common chimpanzee who arrived for study at 10 months old in 1966, named for the home of the University of Nevada, the first of Washoe’s affiliations. A cross-fostering design under human conditions yet utilizing laboratory guidelines for speech exposure and ASL instruction differentiates Project Washoe from other great ape communication studies. Looking at how chimpanzees used gestures in the wild, coupled with knowledge from past spoken English studies, Project Washoe was devised to teach language entirely free from speech, and great pains were taken to ensure Washoe experienced as little spoken language as possible, with all interactions directed at her or between researchers conducted entirely in ASL (Gardner and Gardner 1985).

One year of work with Washoe found her capable of appropriately producing over 30 ASL signs. She demonstrated the ability to use these signs spontaneously, stringing two or more together to make requests, answer questions, name objects, and communicate more effectively than any spoken English ape research had yet found (Gardner and Gardner 1971). Work continued with Washoe under a new research team as she moved in 1970 to University of Oklahoma’s Institute of Primate Studies (IPS) in Norman, Oklahoma, and finally, the Central Washington University’s Chimpanzee and Human Communication Institute (CHCI) in 1993. After several years of study, Washoe’s vocabulary comprehension was extensive and she was capable of producing at least 133 individual signs (Gardner et al. 1989).

### Pili, Moja, Dar, Tatu; Loulis

A project with two-fold intention was initiated in 1972 by Gardner and Gardner. Retaining the same scaffolding of strict ASL training, exposure, and testing, the two aims of the project were to replicate and validate findings from studying Washoe and to observe the effects of co-rearing multiple chimpanzees on ASL production and comprehension. Pili died before study completion, but at 60 months into the project, Moja, Dar, and Tatu produced between 120 and 150 signs each, and were able to use semantic categories in a similar manner to Washoe (Gardner and Gardner 1998).

Another chimpanzee, Loulis, was adopted by Washoe in 1979 at 10 months old. Born at Yerkes Primate Research Center in Atlanta, Georgia, Loulis was not cross fostered. Instead, growing up among signing chimpanzees at IPS and later CHCI, Loulis became the first nonhuman to learn language from other nonhumans, two of whom were Washoe and Moja (Cianelli and Fouts 1998).

### Nim

Inspired by signing ape projects but in a sharp departure from the then typical practices of rearing, including cross-fostering from infancy, Neam Chimpsky (Nim), a common chimpanzee, was acquired from a breeding facility days after birth by Herbert Terrace’s team in 1973. Nim’s environment consisted of a variety of language

tutors in several different settings, with training sessions at Columbia University campus classrooms in intensive daily 2-h bursts. Terrace et al. (1979) describes these classrooms as cold and oppressive even from the perspective of humans. Nevertheless, after 4 years, Nim had acquired 125 ASL signs across a range of semantic categories that he used in different combinations.

Later analysis by Terrace, Petitto, Sanders, and Bever (1979) led to the researchers' conclusion that Nim's use of sign did not amount to any true grasp of language. Examining videotape of Nim's interactions that initially looked promising was instead decided to indicate response to cueing from his teachers or purely reward-seeking imitations of ASL. Linguistic analysis by Bever aided in Terrace's conclusion that Nim was incapable of producing any language on his own. Project Nim was quickly disbanded following increasing incidents of aggression from the growing chimpanzee and disillusionment of Terrace, the primary investigator. Terrace remains a staunch critic of all great ape language research and maintains that Nim was never able to produce meaningful ASL (Terrace 2019).

### Koko, Michael

Francine "Penny" Patterson at Stanford University in Stanford, California began work in 1972 with Koko, a western lowland gorilla (*Gorilla gorilla gorilla*). Born in the previous year at San Francisco Zoo on the fourth of July, Koko (Hanaki-Ko, which translated from Japanese to "Fireworks Child") was the first gorilla to be involved in linguistic study. Exposed to both English and a modified ASL dubbed GSL or "Gorilla Sign Language," Koko eventually came to hold over 1000 signs in her vocabulary, sign at least six in combination, and recognize over 2000 English words (Patterson and Cohn 1990).

The Gorilla Foundation in Woodland, California became home of both Koko and Michael, an orphaned western lowland gorilla from Cameroon in 1976–77. Michael was introduced to Koko as a potential mating partner, but he and Koko developed a relationship of kin instead. Michael received signing training and acquired hundreds of signs and English words. He and Koko signed

to themselves and one another. Koko and Michael were able to use sign to ask and answer questions, create new meanings in sign and generalize known signs, use displacement, deceive, and understand abstract concepts (Patterson 1986; Patterson and Cohn 1990).

### Chantek

Born in 1977, the Sumatran (*abelii*)/Bornean (*pygmaeus*) orangutan (*Pongo*) hybrid, Chantek, was part of a University of Tennessee at Chattanooga (UTC) ASL program. Chantek was initially raised without spoken language much in the same way as Washoe and kin and taught signs by modeling. Later, a methodological shift took place wherein most signs were learned by imitation and spoken English was permissible. The ASL used consisted of proper signs but were presented largely in English word order, amounting to a pidgin sign. Nevertheless, Chantek learned at least 140 signs, which he could combine into two- and three-word strings, often used displacement, and evidence suggests he had mental representations of signed concepts (Miles 1990).

## Visuo-Symbolic Language

### Sarah

Brought to the United States and adopted in 1964 at less than 1 year of age for cross-fostering, the common chimpanzee Sarah participated in a new type of nonverbal, nonsigned language development program. In their laboratory at the University of California at Santa Barbara, Premack and Premack (1972) devised a system of symbolically representing English words and concepts as plastic tokens. Gradually, Sarah was taught more complex relational words and instructed in how to combine these plastic chip "words" using real world objects they represented as referents. By using this gentle increase in complexity to the system over time, Sarah was introduced to and eventually able to produce about 130 words, using the chips successfully and appropriately and demonstrated understanding of relational concepts. Questions have been raised

about research design and as to whether Sarah merely participated in associative-naming exercises between objects and chips, which Premack recognized as a possible explanation of Sarah's performance (Savage-Rumbaugh et al. 1980).

### Lana

With the success of plastic tokens as symbolic markers of English words, the Language ANAlog (LANA) project was developed to expand on logographic language for use with primates. Lexigrams, abstract and semantically and syntactically unambiguous, were created to serve as translations for English words. Arranged on a keyboard and "spoken" by selecting keys on a computer with a built-in correlational grammar, the artificial language "Yerkish" was born (Rumbaugh et al. 1973).

The first to use Yerkish and lexigrams was Lana, a common chimpanzee born in 1970 at Yerkes Primate Research Center. Initially trained to string together lexigrams from compatible semantic categories under the rules of Yerkish grammar, Lana was eventually able to use the keyboard to make requests, answer questions, name objects, and comment on her surroundings. She learned at least 140 lexigrams and produced chains at greater than 90% accuracy. She even developed her own way to self-monitor her performance with the board, pressing the ending or final key repeatedly to abort a sentence with incorrectly ordered or mistakenly pressed lexigrams (Rumbaugh and Gill 1977).

### Ai

Across the Pacific, lexigram work was being conducted at the Primate Research Institute of Kyoto University. Ai, a western chimpanzee (*Pan troglodytes verus*) was born in 1976 and imported to Japan where she participated in cognition research by way of language use. Past studies with lexigrams raised questions about the way chimpanzees perceived the world and the types of mental processes great apes were capable of engaging in. Language held promise as one way to examine these questions. Initially, Ai was able to learn eight lexigrams for nouns and mastered a symbolic match-to-sample task. Along with two

other chimpanzees (Akira and Mari) who participated in the project, Ai later mastered color lexigrams, labels, numbers and Arabic numerals, letters of the alphabet, and even developed spontaneous word order preferences (Asano et al. 1982).

### Sherman and Austin

Where many past studies involving lexigram use focused on communication with human researchers, Savage-Rumbaugh et al. (1986) proposed a primary focus on language use between conspecifics. Sherman and Austin, common chimpanzees, were co-reared and began training with lexigrams at 2.5 years and just under 1 year of age, respectively. Problem solving requiring use of the keyboard was used to look at comprehension of lexigrams and appropriate use. Sherman and Austin were able to learn and use lexigrams in this new way and generalize new items into existing semantic categories, providing the strongest evidence up until that point of symbolic representation as opposed to paired associate learning.

### Kanzi

Born in 1980, Kanzi, a bonobo (*Pan paniscus*), was 6 months old when his adoptive mother Matata began training to use lexigrams. She was an adult when she began her training with lexigrams and largely did not meet the goals of the language projects taking place at the Language Research Center (LRC) in Atlanta, Georgia, only learning a few lexigrams reproducible in limited situations. Present during all of his mother's formal training, Kanzi was never formally instructed with lexigrams as an infant. Then, while Matata was temporarily off site for a breeding program, a young Kanzi without his mother to attend to or occupy him began spontaneously using the lexigram keyboard (Savage-Rumbaugh et al. 1986).

After just 1 week of observation, Kanzi was found to effectively use eight different lexigrams. His performance and the naturalistic way through observation that Kanzi learned to use the lexigram keyboard resulted in a shift in the LRC's research protocol. Formal and explicit training was

replaced by an immersive, language-rich methodology. Researchers would go about tasks, keyboard in hand, to continuously model both spoken English and lexigram use, be it to the apes or other researchers. Over the next 17 months, Kanzi acquired a total of 44 lexigrams and used them in 764 unique combinations (Savage-Rumbaugh et al. 1986). Kanzi is estimated to have learned hundreds of symbols, identifying 348 with 89–95% accuracy (Williams et al. 1997) and several signs in GSL, learned from watching videos of Koko. His comprehension of English is in the range of thousands of words, and he has been shown to respond to new sentences that have a multitude of possible meanings depending on the relationship between noun and verb as well as word order. (Savage-Rumbaugh et al. 1993).

### Panbanisha and Panzee

Matata's offspring, Panbanisha, as well as the common chimpanzee, Panzee, participated in an immersive language project involving co-rearing. Born at the LRC in 1985, Panbanisha was raised by Matata for 7 weeks before joining the project. Panzee was born a short time later at Yerkes Primate Research Center and joined Panbanisha at 8 days old. At the LRC, as was developed shortly after the promise of Kanzi's naturalistic learning, this environment was one of English and lexigrams used concurrently and at every opportunity by researchers. Both Panbanisha and Panzee came to comprehend English words upward of 100 and produce over 100 lexigrams as measured by rigorous standards (Brakke and Savage-Rumbaugh 1996).

### Criticism

As great ape language progressed, so did criticism of it. Future studies often were developed to address concerns of the past, the most obvious example of this being that the premise of teaching apes to speak English was abandoned when it was suggested that there may be modalities (signed language, visual symbols) better suited to the inclinations and anatomy of apes. Criticism of

the whole of ape language research as not failing to capture any true ability and as being wishful thinking of overly invested researchers has been a continuous concern (Savage-Rumbaugh et al. 1980). Staunch objectors such as Herbert Terrace continue to reiterate past criticisms of apes' ability to use words outside of repeating back facsimiles of what humans have produced. Terrace (2019) expresses beliefs that language use is not meaningfully understood by apes and all signing and lexigram use is repetition of human behaviors motivated by reward.

Terrace (2019) initially believed Nim was able to produce meaningful signs using ASL, but, upon later examination of recorded videotapes, decided Nim was merely reproducing what he saw his teachers signing at him, induced by cueing behaviors. He argues that Nim's interruption of signers demonstrates that the behavior was merely imitation, intended to evoke a reward or directly ask the caretaker for something (imperative communication). Terrace goes on to claim that, not in any known study, is any ape producing meaningful words when speaking, signing, or using lexigrams. Not the first to be concerned with the implications of Nim's recorded interruptions as evidence of this, many studies specifically state the rate of interruption as compared to Nim's performance (Miles 1990). Rigorous testing has also been used to demonstrate that cueing does not explain language performance, such as Gardner and Gardner (1984), using a double-blind test specifically to ensure there was no cueing behavior from experimenters that may explain the vocabulary of the four chimpanzees studied.

Repeatedly researchers report the "babbling" of cross-fostered apes, (e.g., Hayes and Hayes 1951, 1952; Savage-Rumbaugh 1986) as evidence of practicing signs for improvement in later use. Michael and Koko (Patterson 1986) signed both to themselves and one another in the absence of the research team. In fact, it is reported in many cases, particularly among co-reared apes, that talk between one another occurs in the modality of instruction under non-testing conditions and largely outside of researcher observation, be it ASL (Cianelli and Fouts 1998) or lexigrams (Brakke and Savage-Rumbaugh 1996).

Savage-Rumbaugh et al. (1986) specifically designed the learning paradigm for Sherman and Austin as one that would control for this supposed false vocabulary set and found nonhuman-dependent spontaneity of lexigram usage.

Imitation as the only process by which great apes can produce something that appears to humans as language use would be an indication that apes possess no understanding of the words they are using, as Terrace (2019) implies. Terrace has stated he felt Nim was only acting on an imitative basis to his teachers, another explanation for the interruptions he engaged in (Terrace et al. 1979). Concerns of ape productions as mere association has also been expressed by earlier critiques (Savage-Rumbaugh et al. 1980). Nonimitative behavior is then any that occurs without an example to imitate, as in the case of ape-initiated language use or any instance of waiting until a human's attention is fixed on an ape before using language. Washoe, Moja, Dar, and Tatu, for instance, have been reported as performing attention-getting behaviors such as producing loud noises, then waiting for a researcher to direct gaze toward the loud sound, and finally producing signs (Gardner and Gardner 1998).

In an episodic memory study, several different objects were hidden, one at a time, in different outdoor locations with Panzee's knowledge but out of her reach and hidden from sight (Menzel 1999). Later, after an imposed delay of up to 16 h, Panzee approached human caretakers indoors who were often naïve to the experiment, invoked attention with noises and gestures before further engagement, and then used lexigrams and gestures to refer both to the object's identity and location outdoors. No prompting occurred from human caretakers and no behavior to imitate had been provided. In this case and that of Gardner and Gardner (1998), apes intentionally invoked the attention of humans and then produced signs without first observing a human performing signs or using lexigrams that could be imitated.

Reward-seeking behavior alone is another of Terrace's (2019) explanations for apes as non-language users. The issue could present itself in an extremely skewed ratio of greater imperative than declarative statements. His position is that

human children produce declarative statements at greater frequency, so if an ape is producing imperative statements instead, the explanation is that imperatives get the ape access to things or provide rewards, so this is the production they are most likely to recreate. In contrast to this supposition are cases in which detailed notes of production content were recorded and revealed to produce speech data that is largely declarative, as in the cases of Kanzi, Panbanisha, and Panzee (Lyn et al. 2011).

Food rewards are a specific concern of Terrace, and he states food motivation and constant treat-providing may assist in the formation of word development and be a primary factor in why apes produce signs. The concern about ever-present food is not indicated in the literature. With few exceptions (Premack and Premack 1972), and perhaps Terrace's own Nim (Terrace et al. 1979), food is not an explicit motivator provided to communicative apes. While other rewards may exist in the form of experimenter praise or attention as known agents that held control of resources that may explain the motivation for engaging in language use, to generalize to such a degree does not grasp the whole of the picture in a long-term study. The literature does not indicate food reward was given in response to correct behaviors with the degree of frequency Terrace (2019) implies; these other types of reward have not been established as definitively undermining performance results.

## Conclusion

Great ape language research reached a pinnacle of scope and scale around the turn of the century that is unlikely to ever be matched, at least in comparable form. For apes in the wild, the average lifespan may be 50 years, and this is often extended in captivity. The practical aspects of housing and finances alone stand in the way. Additionally, the ethical and political landscape is changed, as are the questions surrounding cognition, linguistics, and human uniqueness. Still, these studies and those like them will likely continue to be an influence on future cognitive research.

The bulk of great ape language research comes with critique. At the foundational level, many of the most successful ape projects involved cross-fostering, which aimed to promote an environment of development as similar to that of a human child as possible. This allowed natural language learning in early stages of development and also bonded not only the ape to the researchers but the researchers to their apes as well. Rooted in the earliest studies is a built-in attachment, for example, Furness' (1916) orangutan learned to say "Papa" before anything else, and he provides an anecdote about bringing the orangutan into his pool in his arms until she pleaded with her word "Papa" over and over again.

As the research progressed, researchers attempted to create new methods and testing procedures to address the concerns of critics. Varying across the work of different researchers and over time, broadly this can be split into two different categories of instruction and two categories of testing. The first instructional type involves a more traditional or explicit training with object introduction, modeling of the word that refers to the object, and then invocation of the word from the ape student. The second instructional type, such as the shift in paradigm at the LRC, involves a more naturalistic and immersive environment where teaching is imparted in the way many cultures teach human children, primarily based on modeling. Testing or the drawing of conclusions follows a similar dichotomous pattern, with studies like those conducted with Washoe and kin (Gardner et al. 1989) imposing strict and rigid requirements for sign use before classifying a sign as learned, producing a result of an exact quantifiable language achievement. Later researchers such as Miles (1990) being more focused on capabilities and due to the changing nature of the questions being asked – "What are the cognitive capabilities?" – taking the place of "How many signs can be used?" – naturally, more varied dimensions of ability analysis occurred.

Criticisms from researchers such as Terrace have remained relatively consistent, believing apes to have no concept of language or ability to use it outside of imitative contexts and those motivated by food reward. Evidence refuting those claims including double-blind studies of the

Gardners (Gardner and Gardner 1984), self-initiated behaviors as demonstrated by Panzee (Menzel 1999), and word usage directed at self and fellow apes (Patterson 1986) indicates these criticisms have grounds for contest. Great ape language research may not exist in similar form as the future studies of wide-ranging cognitive capabilities progress, but the impact of these 1900s and turn-of-the-century studies is apparent in modern primatology and psychology.

## Language Research: Parrots

Jen Muir

Department of Social Sciences, Oxford Brookes University, Oxford, UK

### Synonyms

[African grey parrot](#); [Birds](#); [Communication](#); [Cognition](#); [Ornithology](#); [Psittacus erithacus](#)

### Definition

A review of language-centered studies on parrots and implications for understanding parrot cognition.

### Introduction

Language-based animal studies have previously focused on teaching language to nonhuman primates in an attempt to understand how language evolved in humans. However, they eventually branched out, using language as a tool to understand cognition in other animals such as dolphins and birds (e.g., Hayes and Nissen 1971; Herman 1980; Pepperberg 1981). Several bird species have demonstrated an ability to imitate human speech, including corvids, songbirds, and, notably, parrots. Parrots (*Psittacidae* sp.) are a family composed of approximately 390 species. Language research on parrots has focused on African grey parrots (*Psittacus erithacus*), particularly the work of Dr. Irene Pepperberg, which used their ability to interface with humans to explore their cognitive ability. This work paved the way for

other researchers to continue examining parrots and their cognition through language. These studies have allowed for an understanding of how parrots learn and how this ability compares to other species, including humans.

### Why Parrots?

Parrots are a suitable study species for language-based research for several reasons. The main reason is parrot's ability to imitate human speech, allowing for limited communication between researcher and subject. This ability has been observed in various parrot species, all of which were found to learn quickly (e.g., Lashley 1913). Additionally, parrots are social animals and display nonsexual affiliative vocalizations with other group members, making them more willing to engage with researchers and build relationships with them (Colbert-White et al. 2014). There is also evidence that parrots learn through social interactions with others, as seen with orange-chinned parakeets (Power 1966). Several neurological features also make them suitable for language research. Despite having small brains compared to other animals used in language studies, parrots have a larger relative sized brain than expected for their body size (Péron 2012). Similar to humans, they also show brain asymmetry and a bias for communication related structures (e.g., Bottjer and Arnold 1985). Together these features make parrot species ideal for examining cognition through language ability.

### Irene Pepperberg's Studies with Alex the Parrot

The most notable subject in language research using parrots was Alex the African grey parrot, who was trained and studied by psychologist Dr. Irene Pepperberg, from 1977 until his death in 2007. Unlike early language studies on apes, these studies with Alex attempted to develop an understanding of animal cognition rather than human language development. Pepperberg's work focused on testing cognitive ability using language as a tool

and teaching Alex to communicate by training him to use English speech.

This training was accomplished by using a Model/Rival technique, which used social interactions with his trainers to demonstrate desired behaviors (Pepperberg 1981). For example, Alex would view one researcher asking another researcher questions about an object of interest, discussing the object name, size, shape, or color. When these questions were answered, the other researcher would be praised or scolded appropriately. Additionally, these roles would be reversed in order to show that either participant in an interaction may ask questions, encouraging Alex to do so himself. When being tested, if Alex correctly identified an item, he was rewarded with either the item itself (helping to intrinsically reinforce the name with the object) or a desirable treat that was requested (e.g., a piece of banana after saying “I want banana”) (Pepperberg 1988).

To ensure accuracy while testing Alex’s understanding of language, several precautions and controls were employed during testing procedures. To avoid Alex forming an association between certain trainers and certain types of questions, trainers would not repeat the same question topic during their trials (Pepperberg 1981). Additionally, objects and questions used in training were randomly ordered by a researcher who would subsequently not administer the training to avoid cuing from trainers and to prevent Alex from preempting certain questions for a topic (e.g., Pepperberg 1990). Questions of the same type were also never repeated within a session, unless answered incorrectly (e.g., several “how many” questions). Randomized order and no repetition of question types also helped to maintain consistency across sessions in terms of Alex’s attention, avoiding behaviors such as preening, interruptions, or discontinuing engagement (Pepperberg 1999). In the case of the trainer mistakenly judging a response as incorrect, Alex was trained to repeat his response, allowing for a second confirming judgment (Pepperberg 1999). Additionally, accuracy is further ensured by another trainer repeating any answer given by Alex, reducing the chance that a similar to correct response is accepted (Pepperberg 1981). A control was also implemented to dissuade Alex from

asking repeatedly for an item rather than correctly identifying the one he is presented with. In these situations, he was allowed four attempts at a correct identification, before moving on, and with no rewards being given for incorrect answers (Pepperberg 1981).

Model/Rival training allowed researchers to test Alex’s ability to label and request items, understand categories, comprehend similarities and differences, as well as understand absence, numbers, and size of objects relative to each other. For example, Alex could successfully identify 100 objects, as well as 7 colors and 5 shapes in approximately 80% of trials (Pepperberg 1999). Additionally, Alex also performed well in recursive tasks in which he was tested on several categories at once (e.g., “which object is shape-b?”) and even when a conjunctive condition was added (e.g., “what object is color-a and shape-b?”) (Pepperberg 1990). Alex also used the term “none” to indicate the absence of an item, despite not being taught this label (Pepperberg and Gordon 2005). Outside of his training sessions, Alex was observed engaging in sound play, often related to labels that he was being taught in training (Pepperberg et al. 1991). Overall, these studies and observations allowed for the examination of African grey parrot’s cognitive abilities in detail.

## Other Subjects

Alongside research on Alex, additional studies were carried out on three other African grey parrots, named Griffin, Kyaaro, and Alo, all previously untrained and varying in age. The aim of studying these individuals was to determine how using a Model/Rival technique was effective for training Alex in order to gain insight into how he learned. This was achieved by breaking the technique down into its major components and then removing one or more to examine their importance (Pepperberg 1994). The components were defined as referencing (e.g., labelling objects and rewards for successful use of labels), context and function (e.g., motivating use of a label through tasks such as requests), and social interaction (e.g., interaction with the subject, which guides

the learning experience) (Pepperberg 1994). Removal of all three components or removal of social interaction, context, or referencing resulted in no learning being observed in experiments with the three subjects, with successful learning only resulting from the presence of all three components (Pepperberg 1994).

Further studies by Pepperberg and colleagues examined the parrots' understanding of labels and, if they assume mutual exclusivity, the belief that a label defines an entire object rather than a specific feature such as color or shape. To investigate this, comparisons were made between how Alex and Griffin were taught labels for objects. While Alex was told features of objects alongside the object names themselves (e.g., ball, red ball), Griffin was taught these labels separately (e.g., ball, red) (Pepperberg 1981; Pepperberg and Wilcox 2000). Consequently, Alex showed no mutual exclusivity when using labels, and Griffin did, responding to questions only with the first label he learned for items.

Another study examined the categorization abilities of two African grey parrots, Shango and Zoe (Giret et al. 2009). They were taught words that either belonged to food (e.g., chickpea), object (e.g., fork), or neutral (e.g., "hello") categories, and then the parrots recorded during and after training sessions to examine their spontaneous vocalizations. Researchers found that Zoe used spontaneous food labels more when faced with food items, and Shango did so for food and object items, suggesting that they grouped items based on edibility.

Giret et al. (2010) next examined how effective different training methods would be when learning labels across ten parrots. Initially, three parrots were trained with the Model/Rival method used in Pepperberg's studies and the other seven used variants upon this. They were also exposed to an Intuitive training method in which items were handled by a trainer while saying their label, a Repetition/Association method, in which items were produced when the subject says a label they've been exposed to, and a Diffusion/Association method, where recordings of labels were played to the parrots (Savage-Rumbaugh and Lewin 1994). They found that the Repetition/

Association method was most effective for learning, while Diffusion/Association failed. However, the researchers noted that Model/Rival was likely less effective due to differing housing conditions and individual circumstances with the subjects compared to Pepperberg's studies.

Other studies have described how African grey parrots are capable of substituting words with similar meanings and uses within contexts, such as "street" and "road" (Kaufman et al. 2013). Vocalizations of an untrained subject, Cosmo the pet African grey parrot, were found to display such substitution in sentences such as "Cosmo wanna," in which she used words such as "talk," "go," and "cuddle." In this situation, Cosmo understood that "Cosmo wanna" symbolizes a request and the words following represent the requested action. Another study on Cosmo found that she used vocalizations depending on context (Colbert-White et al. 2011). For example, when she was separated from her owner, Cosmo would emit vocalizations discussing where she or her owner where (e.g., "where are you"). Outside of studies focusing on Alex, several other researchers have conducted investigations on parrots and language.

## Implications and Similarities to Other Species

The findings of these studies offer insight into the cognitive capabilities of African grey parrots. For example, the ability to understand and switch between categories of labels such as colors and shapes demonstrates a higher-order class concept and an understanding of abstract concepts (Hayes and Nissen 1971). An understanding of how items can be the same or different from each other may suggest a simple understanding of language, as labels must be understood in order to describe relationships between items (Premack 1978). In addition to this, an understanding of absence suggests advanced cognitive development (Brown 1973). This is supported by the ability to compare items relative to each other (e.g., "which color bigger?") in which information about two features are attended to simultaneously. Kaufman et al. (2013) suggest that Cosmo's use of substitution may also suggest

complex cognition. Studies removing elements of Model/Rival training highlight the essential aspects of learning for African grey parrots: referentiality, contextual use, and social interaction. Colbert-White et al. (2011) also demonstrate the importance of social interaction for learning. However, further studies demonstrated that mutual exclusivity occurs when subjects learn labels purely in a context-dependent manner, similar to that of young children (Liittschwager and Markman 1994). Similarly, the use of perceptual features to categorize objects seen in Shango and Zoe resembles the categorization ability of children under 1 year (Madole et al. 1993). Another parallel with language development in children can be seen in Alex's use of sound play outside of training sessions (Pepperberg 1991). As well as similarities to language development in humans, African grey parrots also display cognitive similarities with other species. Nonhuman primate, cetacean, and pinniped species have also demonstrated an ability to comprehend recursive and conjunctive tasks and the relationships between items, as well as use labels and make requests (e.g., Herman 1987). Pepperberg (1999) proposes that parrot cognitive ability is similar to that of primates, cetaceans, and pinnipeds due to their shared long-life history and complex social system.

### Controversy and Limitations of Parrot Language Studies

While language studies on parrots have uncovered much about their cognition, they also have limitations and have been criticized. For example, Hebert Terrace, who previously conducted studies on chimpanzees and language, proposed that Alex the parrot's responses were simply based on external guidance from trainers rather than a real understanding of the task (Smith 1999). However, there were measures taken during the experiments with Alex to avoid such cuing from trainers (e.g., Pepperberg 1990). One frequent limitation of these studies is a low sample number, often only with one subject (e.g., Kaufman et al. 2011). While this is true for studies that aim to compare between groups, researchers have argued that if one individual can perform a task, this suggests

that the species is generally also capable of doing so (Triana and Pasnak 1981). However, repeated experiments and additional subjects can be useful for highlighting issues with methodology, such as in Giret et al. (2010) in which the Model/Rival method failed in one lab involved, but not the other. Other issues may occur due to individual features such as personality, motivation, age, or sex (Cussen 2017).

### Conclusion

Despite limitations and criticisms, language-based studies of parrots have uncovered much about African grey parrot cognition, showing that, contrary to previous beliefs, they demonstrate complex cognition. Examples of their capabilities include referential labelling, making requests, categorization, word substitution, and an understanding of context, many of which are comparable to those of human children. While language studies on nonhuman primates decreased over time, studies of parrot cognition using language are still being conducted today.

## Synonyms

[Closest living relative](#); [Common descent](#); [Hominid phylogeny](#); [Shared ancestor](#)

"Last common ancestor" (LCA) refers to the most recent species from which two or more species share a common descent. The term is most commonly used to refer to the last ancestor that is shared by both modern humans (*Homo*) and our extant great ape cousins, the chimpanzees and the

bonobos (genus *Pan*). Chimpanzees (*Pan troglodytes*) and bonobos (*P. paniscus*) are humans' closest living relatives, sharing approximately 98.6% of their genetic material with us. It is estimated that the *Homo* lineage diverged from the *Pan* lineage only around 5 to 7 million years ago but possibly as early as 8 million years ago (Langergraber et al. 2012; Prüfer et al. 2012). Chimpanzees and bonobos are themselves highly related, and recent research has shown that they even share genetic similarities with modern humans that they do not share with each other (Prüfer et al. 2012). Given their close genetic relationship to humans, both chimpanzees and bonobos represent crucial living models for enabling us to reconstruct our last common ancestor and, moreover, for identifying uniquely human features.

Despite being closely related and showing many similarities, bonobos and chimpanzees also show some striking differences spanning behavior, cognition, physiology, development, morphology, and neural-anatomy (Hare and Yamamoto 2017). Comparing the similarities and differences of the two *Pan* species is important for constructing balanced models of human evolution (Gruber and Clay 2016). Moreover, recent research has highlighted striking diversity and behavioral flexibility among both chimpanzee and bonobo populations (Boesch et al. 2002). Thus, as well as comparing between the two species, it is also crucial to consider behavioral flexibility within subspecies and subpopulations of both species. Taking into account this variation, both within and between species can provide a much more nuanced view of the behavioral flexibility of our great ape relatives, who can be considered to sit along a continuum shaped by various ecological factors within their surrounding environments. This approach can enable a more valid reconstruction of the LCA between *Pan* and *Homo*.

Although a paucity of data has historically prevented models of the hominin LCA incorporating insights from both *Pan* species, numerous attempts have been made to construct models of early hominins using findings from nonhuman primates. Among the first were Washburn and Avis (1958). Most models have traditionally

focused on chimpanzees as the referential model for early hominins (Tanner and Zihlman 1976), although a recent surge of interest in bonobos is now addressing that imbalance (Gruber and Clay 2016). One recent phylogenetic analysis revealed notable stasis on *Panin* evolution and that bonobos have undergone fewer changes in their musculoskeletal anatomy as compared to chimpanzees and, thus, may be a more appropriate model, at least anatomically, for the last common ancestor (Diogo et al. 2017).

Based on similarities between chimpanzees and bonobo social systems, it is estimated that the LCA likely lived in a fission-fusion hierarchical social system, where both males and females competed for available mates and food resources (Boesch et al. 2002). Shared presence of complex tool use in both bonobos and chimpanzees indicates our LCA was likely to have been a competent tool-user (Gruber et al. 2010). Regarding reproductive behavior, modern humans do not display the conspicuous sexual swellings seen in *Pan* species. Whether this has led to more pronounced concealed ovulation in humans is under debate, particularly because this trait is present to some extent in the prolonged swelling stages of both *Pan* species, especially bonobos. Although the pressures that led to concealed ovulation remain uncertain, it seems reasonable to assume that our LCA lived in a complex social system in which sexual selection highly influenced social interactions and both sexes developed strategies to prevail in this competition. Species differences in intersexual and intra-sexual social bonding suggest that behavioral flexibility probably was present in our LCA. Interpopulation and intersex variability in our LCA probably enabled them to adapt patterns in sociality in response to prevalent social and ecological conditions, further enhancing their success in radiating on the planet.

Latent inhibition (LI), a phenomenon discovered in Pavlovian conditioning, refers to “the detrimental effect of passive, nonreinforced preexposure of

a stimulus on the subsequent ability of an organism to form new associations to that stimulus” (Lubow 1989). Behaviorally, repeated non-reinforced preexposure of the to-be-conditioned stimulus (CS) produces a decrement in learning performance (Lubow and Moore 1959; Lubow 1989; Lubow et al. 1981). The phenomenon is also known as the CS-preexposure effect.

LI has been evaluated in different experimental preparations such as conditioned suppression, conditioned avoidance, and conditioned taste aversion, among many others. This phenomenon has been widely seen in nature, principally (but not exclusively) in mammals, suggesting an evolutionary behavioral mechanism in order to grasp relevant stimuli or events and avoid irrelevant ones in ecological niches (Lubow and Weiner 2010). LI is biologically significant and a relevant psychological phenomenon because it allows the organism to generate faster responses to new rather than familiar stimuli. In a changing environment, organisms must learn to respond properly to new stimuli, which may signal danger, food, safety, etc.

## Background

The CS-preexposure effect was first reported by Lubow and Moore in 1959, who labeled it latent inhibition. It comes from a study designed to evaluate “latent learning” in an animal model. The goal was to explore if learning would happen without reinforcement and whether reinforcement itself was necessary for it, as well as to establish potential differences between learning and performance. Lubow and Moore reported a series of experiments in which subjects (i.e., goats and sheep) received nonreinforced preexposure to a single stimulus (i.e., a flashing light or a moving rotor, counterbalanced), expecting to see an increment in subsequent learning (i.e., conditional leg flexion to a mild shock) involving the preexposed stimulus. This was already observed in other learning situations, such as maze solving and problem-solving tasks, among others. Nevertheless, they observed the opposite results: Subjects reached the response criteria slower when they were previously preexposed to the stimulus. The authors

proposed that the lower rate of subsequent conditioning of the preexposed stimulus compared to the novel stimulus was a function of the learning that occurred during the nonreinforced presentation of the stimulus by itself (Lubow and Moore 1959). In short, LI comes from early experiments of latent learning, in which the term latent was used to designate the learning that “appears” later when an adequate test is performed, and the term inhibition was used to describe the subsequent learning decrement.

### Conditions for Latent Inhibition

In LI experiments, stimuli (pre) exposures are not followed by a significant event, which is common to other learning phenomena, such as habituation, learned irrelevance (preexposure of both unconditioned stimulus [US] and CS), extinction, and perceptual learning, among others. Three features differentiate LI from those other learning phenomena: the conditions for producing it, the conditions for measuring it, and the direction of the differences between groups (Lubow and Weiner 2010). Thus, to demonstrate LI, it is needed to preexpose (either) a target stimulus in one of two groups of subjects or participants, with the other group working as a nonpreexposed control group (a between-subjects experiment); or b) a target (i.e., preexposed) and a control stimulus in a single group (a within-subject experiment). Then, both groups learn an association between the target stimulus and the US (i.e., acquisition). Hence, when the conditioned responses to the target stimulus are compared in both conditions, subjects or participants in the CS-preexposed group respond less or slower than subjects or participants in the control group, showing evidence of LI.

### Theories of Latent Inhibition

The most traditional psychological learning theories can account for the general CS-preexposure effect, and their explanations can be clustered in two families depending on whether the phenomenon represents a failure to learn an association (acquisition-

focused perspective) or a failure to manifest an association (retrieval-focused perspective).

From an acquisition-focused perspective, LI represents an acquisition deficit in which the organism learns to reduce CS processing due to its preexposure during the acquisition or training phase. During the preexposure and conditioning phase, some mechanisms affect the succeeding associability of the preexposed stimulus, due to a loss of salience from an attentional process. All these different models are focused on the attention of the organism to explain LI. Some theories highlight the reduction of attention (e.g., Mackintosh 1975), the loss of associability (e.g., Pearce and Hall 1980), the conditioning of inattention (Lubow 1989), and habituation (e.g., Wagner 1978), to explain LI. Wagners approach puts the focus on the attention to the US, while Pearce and Halls and Mackintoshs theories focus on the attention to the CS. Lubow assumes that the change in attention to a stimulus is continuous and has no separate processes and that the absence of reinforcement reduces the attention to the repeatedly presented stimulus.

From a retrieval-focused perspective, response reduction in LI is due to an interference effect that affects performance at the moment of retrieval rather than during acquisition. That is, organisms learn from both the nonreinforced (CS) and the reinforced trials (CS-US), and reduced conditioned responding is determined by what happens at the moment of testing. At test, both acquired associations concerning the CS (CS and CS-US) are retrieved and compete for expression, interfering with each other (Bouton 1993; Miguez et al. 2018; Miller et al. 2015). The retrieval-focused perspective is supported by two complementary types of evidence, one supporting the idea that LI is affected by changes of context between the preexposure and the acquisition phases, and another supporting the idea that LI is affected by changes in time intervals (i.e., delay or no delay) between the acquisition and test phases (e.g., Miller et al. 2015).

In brief, the acquisition- and retrieval-focused perspectives lie on the premise that something is learned during the preexposure phase but differ on how what was learned is expressed as behavior later (i.e., conditioned response).

## Relevance

LI as a conditioning phenomenon has been important for the development of modern learning theories. Moreover, this phenomenon has been useful to understand some mental disorders such as schizophrenia, and consequently, explain the positive symptoms of this disorder. It is assumed that the process underlying LI is dysfunctional in patients with schizophrenia, that is, they exhibit an inability to avoid irrelevant stimulus (i.e., to show LI; Lubow and Weiner 2010).

Last, LI can be relevant as a preventive technique to avoid the acquisition of fears and phobias (e.g., dental phobia, school fear, veteran post-traumatic stress disorder, etc.). Preexposure of stimuli and situations that are expected to be associated with aversive experiences in the future (e.g., dentists office, school, war zone) could reduce later fear acquisition to those stimuli and situations (Lubow and Weiner 2010).

## Synonyms

[Blodgett effect](#)

*Latent learning* refers to changes in potential for behavior that remain hidden or unmanifest until some later test. Although latent learning is best illustrated by the effects of classroom instruction or similar situations in which individuals acquire knowledge or skills that are not demonstrated until later, when they are tested, the concept is

rooted in maze-learning studies with rats, almost 100 years ago. The phenomenon was important in the emergence of neobehaviorist and cognitive frameworks.

## Background

The term “latent learning” was coined by Blodgett (1929) to describe the sudden improvement in rats’ maze performance that accompanied the introduction of a previously withheld reward. Blodgett ran three groups of rats through a maze and measured the number of blind-alley entrances that occurred each day. The first group, a control, received a reward for each successful run of the maze. The second group was not provided a reward until the third day of maze exposure, and the final group was not rewarded until the sixth day. The control group demonstrated the typical pattern of maze-learning errors: high error rates on the first several trials, followed by a steady decline in errors. The other groups showed little evidence of learning prior to the introduction of food rewards; however, both experimental groups showed an immediate and steep decrease in errors once successful runs were rewarded. Within 2 days of reward introduction, each groups’ performance was indistinguishable from that of the control group, meaning that the rate of improvement was greatest for the experimental groups. Blodgett used the word *latent*, meaning hidden or concealed, to describe the learning that must have occurred on earlier nonrewarded trials but that was not manifest in performance until the delivery of food.

This was a result (also called the Blodgett effect) that was difficult to accommodate into the dominant learning frameworks of the period. The prologue to contemporaneous attitudes about learning included Pavlov’s seminal classical conditioning studies, and though Pavlov himself generally dismissed psychology, his method had found favor with psychologists like John B. Watson who were dissatisfied with earlier introspective and mentalistic approaches (Brennan 1994). Many studies demonstrated the learning of stimulus and response events that occurred together and described the effects of

frequency, intensity, and timing on the learning of the stimulus-response relation. In opposition to this, contiguity perspective on learning was Thorndike’s catalog of learning principles in general and his famous Law of Effect in particular (Thorndike 1911, 1927). Thorndike postulated that stimulus-response connections were differentially reinforced by the consequences of a response: behaviors that resulted in annoying outcomes were not as strongly connected to stimulus conditions as were responses that produced more satisfying outcomes. A great deal of evidence was generated in support of differential reinforcement as the primary predictor of trial-and-error learning, which some interpreted as indication that learning could not occur in the absence of positive or aversive consequences of behaviors. The most cogent and influential summary of these perspectives on learning was provided by Skinner (1938), who described the stimulus-stimulus associative learning as Type S (Pavlovian, respondent, or classical conditioning) and the stimulus-response learning as Type R (or operant conditioning).

Some contemporaries of Skinner willingly embraced behaviorism’s basic tenet, namely, that observable behavior constituted the primary datum for the science of psychology but were willing also to allow a role for inferred variables in explaining how associations between stimuli and/or responses are formed and altered. These theorists, sometimes referred to as neo-behaviorists, embraced “logical constructs, intervening variables, or symbols” (Hull 1943, p. 21) such as habit strength, frustration, hypothesis, and goal in describing the mechanisms of behavior change. Clark Hull and Kenneth Spence, for example, described learning in terms of reaction potentials, which could be mathematically expressed as a function of factors like stimulus intensity, motivation, drive strength, and habit strength (Hull 1952; Spence 1944). Their framework struggled to accommodate findings of latent learning like those reported by Blodgett, as Hullian learning was incremental rather than sudden and depended on reinforcement by way of need-reduction (or drive-reduction). Proponents of the Hullian view scrambled to explain latent learning, appealing to needs like curiosity or an

animal's desire to return to its home cage as potential drives to be reduced. They postulated Hullian constructs like fractional anticipatory goal responses, surrogate responses, momentary effective reaction potentials, goal gradients, and shifts in incentive to explain the rapid learning shown by rats in Blodgett's latent learning paradigm (e.g., Le Ny et al. 1970; Seward 1947, 1949). However, other researchers found these theoretical accounts to be unsatisfying, logically inconsistent, and inadequate to account for the phenomenon (e.g., Buel 1938; Deutsch 1956a, b; Wolpe 1953).

Alternatively, Edward Tolman (in whose laboratory Blodgett made his discovery of latent learning), emphasized the acquisition of expectations, cognitive in nature, that were reinforced via confirmation rather than reward (Tolman 1932). Tolman, who is typically called a neobehaviorist but who preferred the label of the "molar behaviorist," explained latent learning by postulating that the rats learned about the spatial arrangement of the maze in the absence of food reinforcement. Rats that had acquired this latent cognitive map of the maze were thus advantaged over naïve animals when the time came to learn the path to the baited goal box. In contrast to the reinforcement-dependent learning of Thorndike, Skinner, and Hull, Tolman and other proponents of cognitive explanations of latent learning emphasized the importance of internal representations and expectations rather than overt reinforcement for learning. In the words of Wolpe (1953, p. 340), the Hullian view "loses sight of the fact that the events that intervene between stimulus and response take place inside the organism, and that consequently behavioral antecedents may have intraorganismal consequents without behavioral consequents." For Tolman and similar theorists, these explanations and others stimulated intense, decades-long debates and inspired an entire body of research dedicated to the latent learning phenomenon. A comprehensive review of this work was conducted by Thistlethwaite (1951) who argued that latent learning experiments took on four distinct forms. One type of latent learning experiment was collectively termed "the Blodgett variety," as they were iterations of Blodgett's

landmark study (Thistlethwaite 1951, p. 99). The first of these was conducted by Tolman and Hoznik, in which they employed a 14-unit T-maze, a larger sample of animals, and two control groups instead of one (Tolman 1948). The first control group received food throughout the experiment, and the second control group never received it. The experimental group, which received food beginning Day 11, demonstrated the same pattern of responses as Blodgett's rats. That is, they did not appear to learn much of anything the first 11 days of the experiment, but on Day 12, their performance improved dramatically. Several additional experiments were carried out using this procedure, and these produced similar findings.

A second theme in latent learning experiments involved the use of satiated animals for training and the subsequent food or water deprivation of these animals for testing. For instance, Spence and Lippett (as reported in Tolman 1948) conducted an experiment in which water and food were kept in separate alleys of a simple Y-maze. During the training period, satiated rats ran the maze four times a day (two trips down each alley) for a week. At test, one group of rats was deprived of food and the other of water. Within a single trial, hungry rats immediately traversed the maze to the food alley, while the thirsty rats moved directly to the water alley. As in earlier experiments, it would seem that, unreinforced, the rats learned the location of food and water within the maze, and once suitable motivation presented itself, they navigated directly to the item in need as though they were using a cognitive map. Similar experiments yielded a mixture of positive evidence for latent learning and more ambiguous findings that, for one reason or another, remained open to interpretation.

In a related design, some experimenters baited mazes with food and/or water, goals which were either relevant or irrelevant to food- or water-deprived rats. After a time, the rats' need states were alternated (i.e., a previously hungry rat was now kept thirsty, and vice versa), and they were tested in the same maze to determine whether, in the course of learning the location of a previously desired reward, the rats had learned the location of

the irrelevant goal. Some success with this approach was reported, but other attempts did not produce evidence for latent learning.

A fourth type of design commonly used in latent learning experiments was deployed by Haney (1931). Haney allowed an experimental group of rats to occupy a maze for 18 h daily for four consecutive days and found that they made significantly fewer errors at test than did controls. Variations of this experiment included the use of both longer (Buxton 1940) and shorter exploratory periods, doors to prevent route retracing (Daub 1933), or manipulation of cues within the maze (e.g., Buxton; Seward 1949). Familiarity with the maze under conditions of non-reward seemed to result in latent learning with a fair degree of consistency (Thistlethwaite 1951).

Interest in latent learning eventually waned. However, researchers are still asking questions about latent learning today, though it would seem that the interest stems from slightly different orientations. Some psychologists and neuroscientists use latent learning procedures for the purposes of evaluating cognitive impairments that occur as a result of aging (Smith and Stouffer 2014; Stouffer and Helsey 2013) or of particular pathologies like renal failure (Jones et al. 2015). In a similar vein, the effects of particular substances on latent learning performance have also been evaluated (e.g., Luchiani et al. 2015; Malin et al. 2015). Others have explored latent learning in understudied species, including ants (Franks et al. 2007) and zebrafish (Gomez-Laplaza and Gerlai 2010), or in understudied domains like auditory perception (Molloy et al. 2012). Still others have induced lesions to elucidate neuroanatomical structures underlying latent learning in spatial tasks (Kimble and Greene 1968; Kimble et al. 1982). Despite the fact that these recent experiments used latent learning procedures for purposes other than revision of learning theory, the family of experiments dealing with latent learning for learning's sake has not gone entirely extinct. Rather, it seems to have found a permanent home in the domain of spatial learning, where experimenters have combined technologies old and new to evaluate constructs derivative of Tolman's cognitive map. Jensen (2006) reviewed

some of this research, but beyond these studies, cognitive maps have recently been invoked to describe hippocampal processing (Dabaghian 2016), to clarify spatial learning in visually impaired populations (Papadopoulos et al. 2017) and discussed for use in artificial intelligence (Villacorta-Atienze et al. 2015). Some still deal directly with the rat and the maze (Grieves and Dudchenko 2013). For those looking for a comprehensive treatment of the topic, Kitchin and Freundschuh's (2000) book might prove useful.

In terms of critical reception, the primary goal of researchers interested in the topic was to outline the conditions that facilitated latent learning in hopes of refining learning theory (Chaplin and Kraweic 1960; for a review of these conditions, see Thistlethwaite 1951) and there is some lingering question as to whether or not that goal was accomplished. Of course, the substantial investment of research effort into latent learning experiments did not pass without criticism. Jensen (2006) suggested a few reasons latent learning research might have been largely abandoned in the mid-1960s, including the idea that the debate itself had reached an impasse and the notion that preferences in experimental apparatus had shifted away from the maze toward other, more sophisticated methods. Further, there is some indication that more recent conceptualizations of latent learning and its place in the broader zeitgeist has been widely misrepresented (Jensen 2006), perhaps due to its close ties to behaviorism, a school of thought that, some argue, has also been commonly misunderstood (Abramson 2013).

Criticism aside, it is fair to say that latent learning spawned a generation of inventive experimental and theoretical approaches to learning. Rumbaugh (2002) cited latent learning as a key example of emergents – in contrast to the respondents and operants that Skinner described – and thus a cornerstone of what he called “rational behaviorism.” It also sparked a debate that has recently been reignited, and that is the theoretical justification for the learning-performance distinction. A full review of the learning-performance distinction is beyond the purview of the current undertaking, but a brief description is warranted, as it appears in Tolman's (1932) own description

of latent learning (which, in a footnote, he credited to both M.H. Elliot and Karl Lashley; see, for example, Elliot 1929): “Differential effects are, that is, necessary for *selective performance* but they are not necessary, or at the most in only a very minor degree, for the mere learning *qua* learning which underlies such performance.” This argument has been adopted in the decades since to explain how experimental manipulations can improve performance but not learning (or vice versa; for a review, see Soderstrom and Bjork 2015).

## Synonyms

Lateral intraparietal area

## LIP: A Dorsal Stream Region

An influential idea in cognitive neuroscience is that primates have at least two cortical visual processing streams that differ in both anatomy and function (e.g., Milner and Goodale 1995). Information on the patterns of light that hits the eyes is sent to the primary visual cortex in the occipital lobe at the back of the brain. Some of this information is then further processed in the ventral stream, going ventrally from the primary visual cortex to the temporal lobe. The ventral stream is important for object identification and has thus been dubbed the “what” stream. The dorsal stream, also originating in the primary visual cortex but ending in the parietal lobe, plays a role in representing spatial information and has therefore often been called the “where” stream, but has more recently been called the “how” stream because of its importance in action guidance (Fig. 1).

Spatial distortions from parietal damage have long been known. Holmes (1919), about a hundred years ago, described the symptoms of patients who suffered from gunshot wounds to the posterior and upper parts of the parietal lobe. These patients seemed unable to construct spatial representations from visual information; their eyes would randomly drift instead of purposefully scanning the scene, they would reach for an object in the completely wrong direction, and they would even directly walk into walls as if they had no idea of their position in space.

## Lateral Intraparietal Area

### ► Lateral Intraparietal Region (LIP)

**Lateral Intraparietal Region (LIP), Fig. 1** The primate visual system processes visual information along two processing streams. Both streams originate in the primary visual cortex. The ventral stream reaches the temporal

cortex, while the dorsal stream goes toward the parietal cortex. The lateral intraparietal region (*LIP*), a brain region near the endpoint of the dorsal stream, lies on the lateral bank of the intraparietal sulcus

Initially it was thought that an all-purpose spatial representation resided in the posterior parietal lobe. However, primates are capable of complex interactions with their environment. Complex action capabilities might require not just a single representation of space, but many specialized ways of representing where things are and how to potentially react to them. A monkey swinging from branch to branch presumably needs to have a neural system capable of calculating the direction and distance of the next branch relative to where she is looking, relative to where her hand is with which she intends to grasp the branch, and so on. Since the visual information is originally only available in a retinotopic frame of reference, where nearby neurons tend to respond to light falling on locations close to each other on the retina of the eye, these new spatial representations require the transformation of the original retinotopic space into so-called egocentric coordinate frames, where spatial locations of important things in the world are coded with reference to a part of the animal's own body, such as the eyes, head, hand, trunk, or mouth (Milner and Goodale 1995).

The main function of the parietal cortex in primates is often thought to be to carry out such transformations from sensory signals to a format more directly useful for motor output or action guidance (Cohen and Andersen 2002; Milner and

Goodale 1995; Rizzolatti et al. 1997). Within the intraparietal sulcus, several regions can be found, each of which might mainly encode locations in a reference frame centered on a particular part of the body, such as the head or eye (Cohen and Andersen 2002; Colby and Goldberg 1999). An eye-centered reference frame is obviously of use when deciding where to look next, and the lateral intraparietal region (*LIP*), a region high up in the dorsal visual stream, has been implicated in such eye movement guidance; several other roles of this region have also been proposed, including “higher” cognitive functions such as visual attention.

## Anatomy

As the name implies, the lateral intraparietal region lies on the lateral bank of the intraparietal sulcus (Andersen et al. 1985). The region has been heavily studied in the macaque monkey, but homologous regions are thought to exist in the human brain; human intraparietal regions IPS1 and IPS2 are likely candidates as these regions show various functional similarities with area *LIP* in monkeys (Silver and Kastner 2009).

*LIP* has sometimes been further subdivided into a ventral (*LIPv*) and a dorsal zone (*LIPd*) based on differences in architecture, connectivity,

and function (e.g., Chen et al. 2016; Lewis and Van Essen 2000; Webster et al. 1994). For example, LIPv has strong reciprocal connections to brain regions involved in visual motion processing, including area MT, while LIPd might be relatively more connected to particular regions of the ventral stream (Lewis and Van Essen 2000; Webster et al. 1994). Anatomical differences as well as potential different functional roles could indicate that LIPv and LIPd are two separable brain regions.

## Visual Orienting

Orienting was originally considered to be a non-specific reflex that involved turning the eyes, head, and ears (for animals whose ears prick up) to the direction of stimulation (Sokolov 1963). Orienting in primates might mainly rely on shifts in eye position, although orienting can more broadly be thought of as engaging with an outside source through coordinated overt bodily movements and covert attentional deployment for the purpose of information gathering. LIP is generally thought to play an important role in visual orienting, in particular visuospatial attention and saccadic eye movements (jerky eye movements that rapidly change the location of gaze), although the precise function of this brain region is still widely debated (see Bisley and Goldberg 2003, 2010; Colby and Goldberg 1999; Gottlieb et al. 1998).

LIP is well situated to guide orienting based on visual information. It has structural connections with several visual areas such as V2, V3, V4, and MT (Lewis and Van Essen 2000). It is also connected to areas implicated in oculomotor behavior such as the superior colliculus (SC; Ferraina et al. 2002; Field et al. 2008), the frontal eye fields (FEF; Lewis and Van Essen 2000; Ferraina et al. 2002), and the cerebellar oculomotor domains (Prevosto et al. 2010). LIP appears to mainly represent space in an eye-centered coordinate frame, useful for calculating where important things worth attending to and looking at are relative to the center of gaze (Cohen and Andersen 2002).

An LIP neuron might show light-sensitive, memory-related, and/or saccade-related activity, responding vigorously when a visual stimulus is shown in a particular location relative to the center of gaze, when no stimulus is currently shown in a particular location, but this location has to be memorized, or before, during, or after a monkey makes a saccadic eye movement to a particular location (Barash et al. 1991). A preferred spatial location of an LIP neuron can be referred to as the neuron's receptive field (more emphasis on visually evoked responses) or response field (less emphasis on visually evoked responses) or just simply the neuron's RF. Neurons in LIP can however transiently shift their spatial representations immediately preceding an intended saccadic eye movement, where a neuron might briefly code for a location not relative to the current center of gaze, but relative to the immediate future center of gaze were the saccadic eye movement is to be executed, a process known as remapping (Duhamel et al. 1992). LIP might thus be said to have the available machinery to represent space not just relative to current eye position, but also relative to the center of a "virtual eye." This predictive remapping might help with the integration of visual information across eye movements and contribute to the apparent stability of the visual world even when the eyes jump around a visual scene.

Although LIP neurons tend to be light-sensitive, in the sense that their activity generally increases when a visual stimulus appears in their RF, there is some indication that visually related activity might not primarily represent the visual properties of a viewed object. Instead, it might mainly indicate the priority assigned to a location and/or the object occupying that location; the activity of neurons within LIP as a whole could thus serve as a priority map (Balan and Gottlieb 2006; Bisley and Goldberg 2010), where visual stimuli in different locations are assigned different weights based on their salience, current task demands, as well as other factors such as long-term experience (Fig. 2). High priority might thus be assigned to an object in a particular location if it is visually striking (such as when viewing something bright among dark things or dark among

**Lateral Intraparietal Region (LIP), Fig. 2** Prioritizing visual information. Panel (a): In this hypothetical example, the task is to find the *black* crayon among several other crayons. Panel (b): A schematic depiction of a hypothetical priority map, where darker colors signify greater priority. As *black* is a behaviorally relevant feature in the visual search task shown in panel A, anything *black* in the original scene is assigned a high priority value. However, one crayon is noticeably different from all of the rest due to its larger size. As this object is visually salient even though it is not the searched-for object, it could also be assigned a relatively high priority; all things equal, something that stands out from the rest of the environment is worth exploring. If this object would fall within the RF of a particular LIP neuron (RF1), one might expect this neuron

to increase its activity, signifying high priority; the same is to be expected from a second LIP neuron whose RF lies in the location of the searched-for target color (RF2). However, a third LIP neuron – whose RF encompasses an inconspicuous object not directly relevant to the current task – might not become particularly active, signifying the low priority assigned to the object in this location (RF3). An object within a location assigned the highest priority, as represented by the activity of a population of LIP neurons, might then be selected to become the focus of attention as well as the target of an animal's saccadic eye movement. The original crayon images were designed by [Vexels.com](http://Vexels.com) and are used in the current images with the consent of [Vexels.com](http://Vexels.com)

bright things) or behaviorally relevant (such as when an object's visual features match those of a searched-for target). If LIP mainly serves the role of a priority map, LIP activity might neither primarily represent visual attention nor the intention to move the eyes, a subject of some debate. Instead, it could provide information on where important things might be found, information which can then be utilized to orient the eyes and attention to the most active location of this priority map (e.g., Bisley and Goldberg 2010).

Visual attention and eye movements are highly related, so that when something catches attention, it generally also catches the eye. It might therefore make sense to use a single common priority map both for attentional and oculomotor guidance. However, overt (eye movements) and covert (visual attention) visual orienting can be separated, such as when you refrain from rudely staring at a weird-looking person that you nonetheless watch from the corner of your eye. The two subdivisions of LIP, LIPd and LIPv, have been proposed to play different roles in attentional and oculomotor guidance, with LIPd activity being primarily related to the planning of saccadic eye movements to particular locations (overt visual orienting), while LIPv might take part in overt as

well as covert visual orienting (Liu et al. 2010). It has however also been proposed that LIPd is more dedicated to visual processing, while LIPv is more important for saccadic eye movements (Chen et al. 2016). The functional differences of LIPd and LIPv are still not well understood.

## Other Functions

Several studies on LIP muddy the waters when it comes to the precise function of this brain region, as LIP activity appears to be affected by several nonspatial factors that either modulate spatial representations of LIP neurons or are even independent of them (Gottlieb and Snyder 2010). For example, LIP neurons have been reported to be involved in numerical processing, as the activity of several LIP neurons systematically changes with the number of visual elements (Roitman et al. 2007). The activity of LIP neurons can also be affected by learned category membership, such as when a monkey is taught to treat several motion directions as members of two distinct motion categories with an arbitrary category boundary (Freedman and Assad 2009). Some LIP neurons can respond selectively to the shape of

visually presented objects (Serenio and Maunsell 1998; Sigurdardottir and Sheinberg 2015). They can become selective for color arbitrarily associated with a particular behavior (e.g., red means look left; green means look right), and this color selectivity can be separated from a neuron's preferences for saccadic eye movement direction (Toth and Assad 2002). There has also been a body of work looking at the role of LIP in decision-making (Gold and Shadlen 2007). Several other nonspatial factors also appear to affect LIP responses (for further discussion, see Gottlieb and Snyder 2010).

However, it is somewhat unclear to which extent LIP is actively involved in nonspatial tasks and to which extent nonspatial signals in LIP mainly support the region's role in visual orienting (Gottlieb and Snyder 2010). For example, it has been suggested that shape selectivity in LIP might support overt and covert visual orienting, where the shape of an object biases the eyes and attention in a particular direction either due to learning or because of inherent biases (Sigurdardottir and Sheinberg 2015). Surgically removing area LIP also does not prohibit the relearning of a task that requires monkeys to arbitrarily associate colors with actions, suggesting that at least some such arbitrary associations are not dependent on this region (Rushworth et al. 1997). Similarly, Katz et al. (2016) recently showed that while decision-related signals in LIP were strong, they apparently did not play a causal role in decision-making as inactivation of this region did not impair decision-making performance. Instead, silencing LIP neurons affected spatial selection and oculomotor behavior, consistent with this region's primary role in visual orienting.

## Conclusion

LIP is a high-level brain region somewhat far removed from purely sensory- and purely motor-related areas. It is therefore perhaps not surprising that LIP neurons show complex activity related to various aspects of sensation, cognition, and action. However, while LIP might well partake

in other functions, this region's importance for the guidance of overt and covert visual orienting is especially well established. LIP might serve the role of a priority map, where various bottom-up and top-down signals directly influence weights given to objects in different spatial locations, thus biasing where one looks and pays attention.

## Laterality (Handedness)

Garrett W. Milliken

College of Charleston, Charleston, SC, USA

## Synonyms

[Behavioral lateralization](#); [Cerebral asymmetry](#); [Hand preference](#)

## Definitions

*Laterality* is where one hemisphere exerts dominance over the other in the control of a particular behavior or function.

*Handedness* may be defined as the tendency to use one forelimb preferentially for a specific task.

## Introduction

In 1861, Paul Broca published the first paper that tied a cerebral asymmetry to a specific behavioral function and localized that function to a particular hemisphere of the human brain. By finding that “Broca’s area” in the left hemisphere controlled the ability to speak, a new area of research was initiated. Laterality is the condition wherein a function is controlled by a specific hemisphere of the brain. In Broca’s treatise, language is

“lateralized” to the left hemisphere. Human primates (*Homo sapiens*) have an unusually high population-level right-hand preference that is displayed across cultures (Hecaen and Ajuriaguerra 1964). This right-hand preference is highly correlated among fine manipulative tasks and tasks associated with hand/eye coordination (Seltzer et al. 1990). Many have hypothesized that speech and manipulative ability involve similar types of motor control whereby individual systems of muscles must be timed to excite and inhibit in a sequential manner (Kimura 1976). Understanding the progression of the relationship between motor control systems that serve manipulation and speech may best be achieved through the study of nonhuman primates. This is because they have more specialized neuroanatomy for motor control of the forelimb (Nudo and Masterton 1990; Nudo et al. 1995) and a morphological forelimb structure that permits greater mobility of the fingers (Napier 1980).

The primate hand and brain have undergone changes in structure that allow for enhanced neuromuscular control of the fingers. The progression from prehensile grasping to individuated finger movements is exhibited to varying degrees among primate species and offers an opportunity to examine how the hand may have led the brain in evolution (Preuschoft and Chivers 1993). A related aspect of hand/brain function is related to manual specialization wherein a particular hand is favored over the other for a particular task. *Handedness* may be defined as the tendency to use one forelimb preferentially for a specific task. The way in which the tendency is determined has involved using statistics to evaluate whether left- or right-hand usage has occurred significantly more than chance. The statistical procedures have generally utilized either standard scores (z-scores) or a handedness index (HI) (for a review of these approaches, see Hopkins 1999).

Handedness is generally seen to reflect an underlying cerebral lateralization or hemispheric specialization wherein the right hemisphere controls functions on the left side and the left hemisphere controls the right (Hopkins 2007). The lateralization or specialization of each hemisphere may represent evolutionary trends as hypothesized by MacNeilage (2007). This progression

mirrors the evolution of forelimb manipulative abilities and may also be related to the species feeding niche specializations. MacNeilage et al. (1987) believe that the rudimentary form of lateralization that is still evident in Prosimians and specifically in insectivorous vertical clingers and leapers involved a right hemisphere (left-hand) specialization for insect capture and a left hemisphere (right-hand) specialization for postural support. With speciation and pressure to expand the insectivore niche to include fruit or foods that require increased manipulative skill to remove the edible portions from the matrix in which they are embedded, a change in manual specialization was required. This change involved the left hemisphere (right hand) changing its specialization from postural support to manipulative skill and associated refinement in individuated finger movements and a precision type of grip. MacNeilage et al. (1987) proposed that this progression may be seen in the way in which anthropoid primates and especially old-world primates use their hands to forage for embedded food resources where the left hand retains its prehensile grasp on the food item and the right hand manipulates the husk or peel to reach the edible portions. Although there is good amount of evidence to support these ideas in the prosimian literature (for reviews see Ward et al. 1993; Watson and Hanbury 2007), the progression toward a right-hand manual specialization hypothesized among anthropoids is less consistent but becomes somewhat more consistent when hand preferences are interpreted in light of the behavioral task and when body posture is also taken into account (MacNeilage 2007).

Although many researchers support an evolutionary approach to the study of lateralization that predicts a continuity in behaviors tied to cerebral asymmetries within the order Primates, there are those who believe the human language represents a unique ability that differentiates *Homo sapiens* from the rest of the animal kingdom (Corballis 1991). It is proposed that the lateralization of speech seen in human language helps to magnify the associated right-handedness seen in the human population. Because a similar *population-level* trend is not seen in other primate species, this is taken as evidence against the gradual evolution of

primate handedness. McGrew and Marchant (1997) performed a meta-analysis on 241 published primate laterality studies and found that only captive chimpanzees displayed some degree of right-handedness that would begin to approximate the human condition. They also did not find any appreciable phyletic progression toward this right preference and argued against the validity of handedness data derived from captive populations.

Many of the inconsistencies noted in the old-world monkey literature are due to differences in the tasks used to evaluate handedness and whether postures were accounted for. For example, measures of hand preference have generally enlisted a simple food-reaching task that involved the primate reaching for food and then eating it. While this may provide a measure of lateralization related to simple food reaching, it may be the case that a different hand is used to hold the food while it is being consumed or perhaps the feeding task is bimanual with one hand holding food and the other extracting edible portions from the peel. In this sense it is sometimes difficult to assess handedness because the hands are perhaps being used for different elements of the feeding task. It has been demonstrated that factors such as reach posture (bipedal vs. quadrupedal), substrate (arboreal vs. terrestrial), type of grasp (prehensile vs. precision, bimanual vs. unimanual), food type, and size do influence the direction and strength of handedness (Meguerditchian et al. 2013). It is only through careful analyses utilizing multiple measures of hand use that we may reveal factors that may have promoted early forms of lateral preference. It could be the case that the gradualist approach hypothesized in the postural origin theory may be too general with respect to the transition to right-handedness in Anthropoid primates and that several species-specific factors may converge and result in a population-level trend.

## Cerebral Asymmetry

The search for anatomical asymmetries that are indicative of cerebral lateralization has focused on morphological or electrophysiological differences between the hemispheres. The finding that great

apes and humans share a larger area 44 (homologue to Broca's area) in the left hemisphere when compared with the right indicates that at least in chimpanzees and gorillas, a structural lateralization similar to the human condition exists (Cantalupo and Hopkins 2001). Like humans, chimpanzees and gorillas have demonstrated characteristics of symbolic language (Savage-Rumbaugh et al. 1986; Patterson and Linden 1981). Similar asymmetries have not been found in the brains of old-world monkeys, but other interesting facets related to communication have been identified. In a study of rhesus monkeys, metabolic activity was compared between the left and right hemisphere when either control sounds or species-specific monkey calls were played (Poremba et al. 2004). It was revealed that significantly greater metabolic activity occurred in the left superior temporal gyrus but only in response to the monkey calls rather than the control sounds. Rhesus monkeys do not have a similar structure to Broca's area, but these results indicate that there was perhaps a hemispheric specialization for interpreting sounds used in communication that could have preceded the vocal complexities associated with language.

Electrophysiological asymmetries in the hand representation of primary motor cortex (area 4) were correlated with hand preference in squirrel monkeys and involved larger surface area for hand movement and greater spatial complexity of the motor movement representations in the dominant hemisphere (Nudo et al. 1992). Squirrel monkeys do not have a population-level hand preference but the neural control asymmetries were consistent with the preferred hand of each animal tested.

Potential factors that could have preceded motor lateralization may be seen in non-primate species and generally involve lateralized differences in perceptual abilities or social behavior (for review see Rogers and Andrew 2002; Vallortigara 2006). Many studies in rodent, bird, reptile, and amphibian species have found population-level tendencies for pawedness, prey capture, social behaviors related to courtship, and aggression. After more than 150 years of study, much has been written about cerebral lateralized structures and functions, but few phyletic

comparisons reveal a simple evolutionary progression from sensory to motoric lateralization. What is apparent is that lateralized functions and associated cerebral asymmetries do exist and must confer an advantage to the animal in order to be selected for. It may be the case that these selection pressures function differently not only between species but also within individuals of the same species. How the human species became so rigidly lateralized for speech functions remains a valid question for research, but it is also important to understand the factors that influence lateralization in other species as well.

## Laterality Effect (Face Perception)

Heida Maria Sigurdardottir and Bahareh Jozranjbar

Icelandic Vision Lab, Department of Psychology, University of Iceland, Reykjavik, Iceland

Face recognition is an essential skill that in many species is associated with apparently specialized neurological and cognitive mechanisms. This chapter summarizes some of the behavioral and neuroscientific research on laterality effects in face perception, with a focus on face identity processing in humans and animals.

### Laterality Effects: Humans

Certain regions of the human ventral visual pathway, which plays a crucial role in visual recognition, tend to respond vigorously to particular types of visually presented objects, such as buildings, words (in literates), and faces. The most famous face-selective region is no doubt the fusiform face area (FFA) that tends to selectively respond to faces relative to other visual objects. The FFA might however act as a hub in a whole network of face-responsive areas. Two other well-known face-selective regions are the occipital face area (OFA) and the superior temporal sulcus (STS). As can be seen in Fig. 1, all three show a laterality effect with more pronounced face selectivity in the right hemisphere.

### Right-Hemisphere Dominance of Human Face Processing

Neuroimaging, electrophysiology, and behavioral studies all support the general advantage of the right hemisphere in face processing. The face-sensitive N170 event-related potential component is right-lateralized. People also tend to be faster at processing faces presented to the left visual field – which projects to the right hemisphere – compared to the right visual field. Similarly, when

shown chimeric human faces (Fig. 2) composed of either the left or right side of a picture of an original whole face, people are likely to perceive the left chimera rather than the right chimera as resembling the original. Interestingly, this might not extend to the perception of monkey faces, at least not for observers with limited exposure to monkeys, indicating that the laterality effect could be experience-dependent or, perhaps less likely, species-dependent (for the role of experience in visual object recognition, see, e.g., Sigurdardottir and Gauthier 2015). Tachistoscopic presentation of faces in split-brain patients has also confirmed the dominance of the right hemisphere for face recognition. Electrical stimulation of the right fusiform gyrus has been found to induce the conscious perception of faces, while stimulation of face-related regions in the left fusiform gyrus caused a nonface visual change, although this could be dependent on hemispheric dominance for language processing and/or handedness. Research has also shown that unilateral right damage can lead to prosopagnosia (facial recognition disorder), at least in right-handed individuals. There are a few reports of left-handed people with prosopagnosia with unilateral left damage, suggesting the possible role of handedness in face lateralization. However, face-selective regions in left-handed individuals still appear to be right-lateralized, with the exception of FFA that seems to be less lateralized or even left-lateralized in most left-handers.

### Origins of Hemispheric Differences

There is a debate on whether the general right hemisphere dominance for face processing is due to prespecified properties of the neural network (nature) or if it is experience-related and the network becomes specialized after repeated exposure or training (nurture). Unlike selectivity for some other object classes, face selectivity has a delayed developmental trajectory, where lateralized face-selective areas such as FFA, OFA, and STS are not consistently found in young children. It is possible that such a trajectory is predefined, but it could also be due to increased visual expertise with faces, in particular

**Laterality Effect (Face Perception), Fig. 1** Laterality of neural face processing in the human brain. The fusiform face area (FFA), occipital face area (OFA), and the posterior part of the superior temporal sulcus (pSTS) of the left (L) and right (R) hemispheres are shown. The yellow/

orange shows face selectivity, here defined as the contrast of faces vs. nonface objects. (The image is originally from Huang et al. (2014). The image is used according to a Creative Commons (CC BY) license. Copyright © 2014 Huang, Song, Li, Zhen, Yang and Liu)

Original face

Left chimera

Right chimera

**Laterality Effect (Face Perception), Fig. 2** Laterality effects in face perception have been measured by face chimeras. Here, the left and right parts of an original face (author HMS) were used to make two chimeric faces, one

from the left half-face image and one from the right. Humans and some animals tend to choose a left rather than a right chimera as being similar to an original full face

increased reliance on so-called configural processing (perceiving relations among features, such as where the eyes are relative to the nose, although the term might refer to a few distinct processes, see, e.g., Maurer et al. 2002) in which the right hemisphere might excel. The right lateralization of neural face processing has also been suggested to be influenced by competition during reading acquisition between neural representations of visually presented faces and words in the left hemisphere (language processing is generally left-lateralized). Consistent with this hypothesis, some research has indicated that the degree of face lateralization varies with literacy

(see, e.g., Dundas et al. 2013). The lateralization shift of the FFA in left-handers has also been suggested to be a result of reduced left hemisphere neural competition between faces and words. On the other hand, seemingly consistent with prespecified face perception mechanisms, right-lateralized face-selective neural responses have been reported in young infants well before reading acquisition. Nonetheless, depriving the right – but not the left – hemisphere of visual input during infancy selectively impairs later ability for configural processing of faces (specifically, sensitivity to spacing of facial features). Thus, laterality effects in face processing might be

driven by a mixture of predefined hemispheric biases and visual experience.

### Hemispheric Specialization

Although various studies have shown the dominance of the right hemisphere in face processing, the right and left hemispheres are likely both involved in face recognition but in different ways. The right hemisphere is superior at processing low spatial frequency information from faces, while the left hemisphere appears to be more specialized for processing high spatial frequencies. Related, while the right hemisphere is more involved in configural processing of faces, the left hemisphere might show superiority for featural or analytic processing of faces. When faces are inverted, judging their configuration becomes difficult, and this eliminates or reduces the right hemisphere advantage. These findings are in line with neuropsychological evidence, indicating that prosopagnosic patients, who tend to have right hemisphere lesions, might perform equally well when matching upright and inverted faces (no face inversion effect). Divided visual field methodology studies have also shown the superiority of the left hemisphere when feature-by-feature processing of faces was induced by task manipulation. For more information on laterality effects in human face perception, see, e.g., Gainotti (2013) and Júnior et al. (2014).

### Laterality Effects: Animals

The visual system of nonhuman primates shows many similarities with that of humans. The Rhesus macaque system is best documented, but visual face processing in other primates, other mammals such as sheep, and even other non-mammalian species, has been studied. For reviews on face processing in animals, see, e.g., Kendrick (2006), Leopold and Rhodes (2010), Parr (2011), and Tate et al. (2006).

#### Primates

Chimpanzees, like humans, can quickly identify individual conspecifics by their faces. Chimpanzee face recognition is impaired by distortion of the configuration of faces. Like

humans, chimpanzees find it more difficult to recognize inverted compared to upright conspecific and human faces (face inversion effect), often thought to be due to disruption of configural processing which in humans is right-lateralized. Accordingly, some evidence supports that face processing in chimpanzees is right-lateralized. For example, when chimeric chimpanzee or human faces were made by vertically flipping a half-face around the midline (see example in Fig. 2), chimpanzees showed a tendency to choose a left rather than right face-half chimera as being more similar to an original centrally presented whole face. This probable right hemisphere advantage might increase with age and/or experience with faces. Accordingly, configural face processing in chimps might be experience-dependent, as no reliable face inversion effect in chimps was found for the faces of an unfamiliar species (brown capuchins), and their configural processing also appears to be greater for chimpanzee faces than human faces. It should be noted that chimpanzees tend to be right-handed, and handedness could possibly be related to brain asymmetries in face processing. There are however some apparently conflicting results, where chimps were equally likely to match a left and right chimera to an original whole face.

Rhesus macaques can also distinguish between conspecifics based on their faces, and a whole network of interconnected face-responsive regions has been mapped in the macaque brain. Some behavioral studies have reported a lack of lateralization of face processing in macaques. For example, a study using chimeric faces (Fig. 2) revealed that macaques failed to show asymmetry for face matching with either monkey or human faces. Possibly related, a face inversion effect in macaques has not consistently been found (although some studies do report such an effect), which has been interpreted in favor of less reliance on configural – and presumably right-lateralized – processing as opposed to featural processing. Consistent with this, even infant macaques with no previous exposure to faces can discriminate between faces based on both facial features and their spacing or configuration. Early work on split-brain Rhesus

macaques also found no lateralization for learning to discriminate photographs of monkeys. fMRI studies have also reported bilateral face-selective activity in the monkey temporal cortex, although some do report more extensive right-hemispheric activation for faces. There are also some split-brain studies that support right-hemisphere superiority in macaques, particularly for upright as opposed to inverted faces. To complicate matters even further, early single-cell recordings in macaques reported a more abundant population of face-selective neurons in the left compared to right temporal cortex, hinting that monkeys and humans might use a qualitatively similar mechanism for face processing with a different direction of cerebral asymmetry. Left hemisphere lateralization for learning to discriminate monkey faces has also been reported specifically for female macaques. The lateralization of face processing in other monkey species has not been extensively studied, although stronger activation in the right temporal cortex in vervets has been reported for the passive viewing of faces in comparison to nonface objects.

### Nonprimates

Some nonprimate species are reported to have right-lateralized visual face processing. Domestic dogs can identify the face of their owner, and many dogs discriminate between the face or head of their owner and that of another familiar person. Dogs show greater activation in a putative dog face area of the right temporal cortex when observing faces of dogs or humans as compared to nonface objects. Sheep also show greater activity in the right compared to left inferior temporal cortex when viewing upright faces but not inverted faces. Sheep also recognize conspecific faces more by the left visual field (right hemisphere advantage), and this effect is stronger for familiar faces. Interestingly, while sheep can discriminate between human faces, they show a smaller inversion effect for human faces than seen with sheep faces and in general show little indication of configurally processing human faces. Sheep also have no left visual field advantage or even a slight right field advantage for human faces. This might suggest a role of expertise for developing a right brain hemisphere advantage

for the configural processing of faces but could also be consistent with an innate species-specific mechanism. Laterality effects in face processing have rarely been studied in nonmammals, but there are some studies that provide support. For example, the right hemisphere of chicks appears to be better equipped for visually processing information relevant to the recognition of other chicks, and several species of teleost fish are reported to mainly use right-side brain structures when viewing conspecifics.

### Summary

To summarize, while the lateralization of face processing in nonhuman primates is somewhat controversial, humans appear to share right hemisphere lateralization for face processing with animals as diverse as dogs and sheep and possibly even some birds and fish. Although by no means conclusive, these results could indicate that some face processing capabilities might be shared among mammals, and some researchers have even suggested that lateralization of the visual analysis of stimuli provided by conspecifics is shared by all vertebrates (Sovrano et al. 1999).

## Laurie Santos

Laurie R. Santos

Department of Psychology, Yale University, New Haven, CT, USA

Laurie Santos is a cognitive psychologist who studies the origins of human cognition. Specifically, Dr. Santos compares human cognitive capacities with those of nonhuman primates and domesticated dogs. She is broadly interested in the question of what makes human cognition unique.

Dr. Santos began studying human psychology from a comparative perspective as an undergraduate student at Harvard. She joined the lab of then Harvard professor Dr. Marc Hauser, where she began studying two species of nonhuman primates: cotton-top tamarins (*Saguinus oedipus*) at Harvard and rhesus monkeys (*Macaca mulatta*) living at the Cayo Santiago Field Station in Puerto Rico. After graduating from Harvard in 1997, Dr. Santos continued studying at Harvard with Dr. Hauser as a graduate student. Her PhD work explored how monkeys represent different kinds of objects. Many developmental psychologists have argued that human learners have mechanisms that allow them to focus their attention on conceptually relevant perceptual inputs during early learning (see reviews in Santos and Caramazza 2002). Dr. Santos's PhD work tested whether nonhuman primates share these domain-specific categorization biases. To do so, she systematically contrasted primates' knowledge of

two different domains of objects – foods (Santos et al. 2001) and tools (Santos et al. 2005). Her work on this topic revealed important similarities in the way that human children and primates reason about different kinds of objects, suggesting that similar (possibly evolutionarily ancient) domain-specific learning mechanisms might be at work across these different populations.

After completing her Ph.D. in 2002, Dr. Santos began a faculty position at Yale University. She set up a laboratory of captive brown capuchin monkeys (*Cebus apella*) and also continued the work she began as an undergraduate working with rhesus macaques at Cayo Santiago. While at Yale University, she began a set of studies testing the nature of primate object cognition and whether primates share human-like representations of object. Over the past few decades, developmental psychologists have learned a great deal about the “core knowledge” abilities that human infants use to represent objects and their motions (see review in Santos 2004). Dr. Santos and her students began testing whether primates shared human infants’ core object reasoning capacities, exploring whether nonhuman primates, like human infants, make accurate predictions about objects and the way they behave. Her early work revealed that primates seem to represent objects in much the same way as human infants. She and her students have shown that adult primates recognize that objects continue to exist when occluded and trace continuous paths in space and time (see Santos 2004 for a review). Her work suggests that nonhuman primate may reason about physical objects in much the same way as human infants; specifically, primates may also represent objects in terms of Dr. Elizabeth Spelke’s principles of continuity, cohesion, and solidity (see Santos 2004).

In addition to making discoveries about primates’ understanding of the physical world, Dr. Santos’s research has also provided important insight into what primates know about the social world. One of the hallmarks of human cognition is our species’ ability to reason about the minds of other individuals, a capacity commonly referred to as a theory of mind (ToM). Although developmental studies have revealed much about the

ontogeny of our ToM abilities, there is still much controversy about the evolution of ToM capacities and the question of whether primates share human-like mechanisms for understanding other minds (see review in Drayton and Santos 2016). Dr. Santos and her students have discovered that primates represent some – but not all – of the psychological states of others (see reviews in Drayton and Santos 2016; Martin and Santos 2016). Specifically, she and her students have found that monkeys recognize what others see, hear, know, and intend but fail to represent others’ beliefs. Dr. Santos’s current work is now focused on better understanding these limitations on primates’ social-cognitive capacities (see review in Martin and Santos 2016).

Dr. Santos is also known for her work on what some have referred to as “monkeynomics” – studying the origins of human economic biases in non-human primates. Specifically, she and her colleagues have gained important insight into the evolutionary origins of some of our species’ irrationalities and economic biases. Dr. Santos’s work discovered that primates share an impressive number of human-like irrational biases. She and her students discovered that monkeys share a human tendency to “rationalize” choices (Egan et al. 2007). She has also discovered that monkeys exhibit many of the same economic biases as humans (see reviews in Lakshminaryanan and Santos 2012). After developing a “token economy” method for testing monkeys’ economic decisions, she and her students found that capuchins frame their decisions in terms of gains and losses and tend to show loss aversion (e.g., Lakshminaryanan et al. 2011). Overall, Dr. Santos’s work has shown that nonhumans show many of the same cognitive biases as humans.

There is one domain, however, in which Dr. Santos has begun to discover that humans may be uniquely irrational – the domain of *social irrationalities*. Classic work in social psychology has shown that humans have the tendency to automatically copy the actions, preferences, and ideas of others. This tendency is useful when others’ ideas and actions are effective but leads us astray when others behave inefficiently or have incorrect ideas. Dr. Santos’s ongoing work is beginning to

show that primates may not have this same tendency to copy others' mistaken actions and beliefs. She has found that rhesus monkeys are not affected by others' mistaken beliefs in the same way as humans (see Martin and Santos 2016). She has also discovered that capuchin monkeys do not fail prey to "pricing biases," the tendency to think that higher priced goods – ones that others like – are more valuable (Catapano et al. 2014). These new results suggest that humans may be unique among primates in our tendency to irrationally copy the unwise ideas and preferences of others.

To better test the origins of our human "social irrationalities," Dr. Santos and her students have recently begun testing a different nonhuman species that may be more attuned to others' social information than primates: *domesticated dogs*. During domestication, dogs were required to learn from humans in some of the same ways as human children learn from their elders. Dr. Santos has thus begun using dogs as an important model for studying the role that social learning plays in the development of both the smart and less smart aspects of human cognition. In December of 2013, Dr. Santos launched the Canine Cognition Center at Yale, a new facility aimed at testing how dogs learn from other social agents, as well as other questions in canine cognition. Using this new canine cognition approach, her lab is currently pursuing new studies aimed at providing insight into the origins of human pedagogy and cultural learning more broadly.

Dr. Santos and her work have been featured in numerous media outlets, such as *The New York Times*, *The Wall Street Journal*, *The Economist*, and *The New Yorker*. She has won numerous awards for science, teaching, and mentorship. She was awarded the Stanton Prize from the Society for Philosophy and Psychology for outstanding contributions to interdisciplinary research. She was named one of Popular Science Magazine's "Brilliant 10," and a TIME magazine "Leading Campus Celebrity." Her TED Talk has well over a million views. In 2016, Dr. Santos was named Head of Silliman College at Yale.

## Law of Effect

Susana Carnero-Sierra  
Universidad de Oviedo, Oviedo, Spain

### Synonyms

Associative learning; Operant conditioning; Reinforcement

### Definition

The Law of Effect is one of the basic laws of learning formulated by Thorndike. It states that a behavior followed by appetitive consequences will tend to be repeated in the future.

### Introduction

Edward Lee Thorndike published an experimental work in 1898 that not much later was explicitly defined as the Law of Effect, as Thorndike stated in his book *Animal Intelligence* (Thorndike 1898, 1911). In this work, Thorndike addressed three relevant topics in learning: the comparative role of learning between humans and other animals, the experimental methods employed to investigate similitudes and differences in behavior between species, and, finally, the Law of Effect (Lattal 1998). All these topics were focused outside the anecdotic method for animal reasoning, as Thorndike effusively defended.

The formulation of the explicit Law of Effect could be seen as a legacy from Darwin's evolution theory (Postman 1947). Thorndike was also influenced by Spencer-Bain's theory, in terms

that the incoming pleasure benefits the animals and they are going to try to achieve it constantly. *The Principles of Psychology* by William James were also relevant for Thorndike's work.

At first, Thorndike understood the Law of Effect in a double view: appetitive outcomes enhance behavior, and aversive ones decrease the frequency of the contingent conduct. But from the data of his experiments with different species, results led to think that the effect of reward and punishment were not exactly equivalent, thus having a different nature (Postman 1947).

### The Origin: The Puzzle Boxes

Thorndike modeled the Law of Effect with his famous experimental series about how several cats escaped from boxes designed to keep the animals inside. This apparatus had different mechanisms that the cats had to trigger if they wanted to escape. In his studies, Thorndike measured how fast the animals escaped and how the reaction time to scape decreased if an appetitive reinforcement was waiting out the box. Puzzle boxes were handmade by Thorndike, and each had a different way to scape. Pulling or pressing one or several mechanisms had the release of the animal from the box as a result. Cats seemed to find the way to scape, following a trial-and-error process. Thorndike could draw different patterns of reaction time to escape, trial by trial and for each subject.

The Law of Effect appeared when all the empirical data from the puzzle boxes were combined. At the same time, Thorndike formulated the Law of Exercise: as more connections are established between the behavior and the pleasant outcome, the stronger the behavior gets. However, after his experiments, the Law of Exercise was discarded, and Thorndike made the Law of Effect protagonist (Postman 1947). The empirical evidence, mainly with cats, dogs, and chicks, led Thorndike to think that the simple practice of a habit was not enough to establish an association. His experimental subjects showed that certain effects or consequences were required to strengthen a behavior (Lattal 1998).

## Implications

The Law of Effect is considered the prelude and the basis of operant conditioning and the subsequent reinforcement theory. Reinforcement is the formal term to designate the consequences of a specific behavior with the aim to strengthen or diminish its frequency. With this law, Thorndike opened a formal discussion about how motivational drives could encourage certain behaviors in animals. At this respect, subsequent theories have discussed the role of concepts such as instinct, hedonistic variables, or purposes in the path to understand the Law of Effect as a motor of behavior.

In the applied fields, educational and clinical matters have widely used the reinforcement theory and the Law of Effect. Additionally, the Law of Effect is also the central issue in animal training. It should be pointed that reward and punishment have been fundamental in educational disciplines, being the central issue for behaviorism and preluding Watson and Skinner's subsequent work (Skinner 1969).

## Learned Affordances

Thomas R. Zentall

University of Kentucky, Lexington, KY, USA

Psychologist James J. Gibson introduced the term affordance in his 1977 chapter “The theory of affordances” and defined it as all action possibilities latent in the environment (Gibson, 1977). Based on Gestalt theories, affordance theory states that the world is perceived not only in terms of object shapes and spatial relationships but also in terms of the possibilities of objects for action.

Objects generally have affordability. The affordance of an object is what one can do with it. The affordance of a static door knob is something that one can hang things on. But the affordance of the door knob changes, if one sees a person turning the door knob. Now the affordance of the door knob is that it is something that turns. Seeing the person pull the door knob after turning it changes its affordances and that of the door. The closed door has limited affordance but once the door knob is pulled and the door is opened the door now provides a new kind of affordance. The door knob now allows the door to be moved in an arc along one vertical edge towards the observer and that movement provides a space through which one can walk. The new affordances allow one to learn that the

door knob turns to the right, that it can then be pulled, that pulling it causes the door to pivot along the right edge exposing an opening through which one can pass. And all of that occurred with minimal reference to the demonstrator. Thus, one does not need to refer to the observer's behavior or to use the term imitation (see section on imitation) to explain how, after observing a demonstration, the observer knows to turn the door knob and pull the door open to pass through to the other side.

In a similar way the observation of a demonstrator rat, for example, pressing a lever can change the affordance of the environment seen by an observer. Observing a lever on an operant panel is likely to provide limited affordance but if one can see another animal pressing the lever, it changes the environmental affordance of the lever from a stationary object to an object that can be pressed downward and that returns by itself. Thus seeing another animal press the lever changes the affordance of the lever. That change in the affordance of the lever may change the probability that the observer will press the lever. Thus, affordance learning is related to stimulus enhancement (see entry on local/stimulus enhancement) in the sense that with stimulus enhancement, the movement of the lever draws the observer's attention to the lever. But affordance learning also implies that the observer can learn about the action of the lever. Thus, the action of the demonstrator changes the affordance of the lever and that change may lead to an increase in the probability that the observer would press the lever but it would not be considered imitation in the sense that the observer had learned about the behavior of the demonstrator through observation.

Affordance learning is related to emulation (see the section of emulation) in the sense that the observation of a demonstrator acting on an object may change the affordance of that object. In the case of emulation, the change in affordance is associated with the outcome obtained by the demonstrator, and if it acts to motivate the observer to obtain the outcome, it may cause the observer to emulate an action that leads to the same result. Once again, although the observer's behavior leads to the same result as

that of the demonstrator, it would not be considered imitation (see Zentall 2012).

## Learned Helplessness

J. Bruce Overmier<sup>1</sup> and Mikael Molet<sup>2</sup>

<sup>1</sup>University of Minnesota, Minneapolis, MN, USA

<sup>2</sup>University of Lille, Villeneuve-d'Ascq, France

The phrase “Learned Helplessness” refers sometimes to a trauma-based empirical phenomenon, sometimes to a cognitive theory about the mechanisms underlying the empirical phenomenon, and sometimes to both at the same time. The empirical phenomenon and the elements of the proposed cognitive mechanism were first introduced by Overmier and Seligman (1967). The basic phenomenon seen in their dogs was a dramatic proactive interference with making and learning coping behaviors, primarily escape behavior, observed a day after having been exposed to 60 unpredictable and uncontrollable 5-sec electric footshocks distributed over an hour. The Learned Helplessness had three features: behavioral, the lack of behavioral coping efforts noted above; associative, a failure to learn the escape response even if they made an escape; and emotional, an apparent passivity to the shocks. Seligman and Maier (1967), in an experiment begun with Overmier (see authors' footnote), showed that the uncontrollability of the shocks was a critical causal feature for the induction of the Learned Helplessness by using the

so-called “triadic design” paradigm that compared three groups: one group (the Master group) received 60 trials with electric footshocks but was able to escape from or avoid any of the footshocks; a second group (the Yoked group) that was exposed to the same number, duration, and intensity of electric footshocks as experienced by the Master group; and a third group (Normal) that was exposed to the shock apparatus for the same session length but received no shocks. When tested in a second phase 24 h later for their ability to escape in a new apparatus, the Master and Normal groups reliably performed well, while the Yoked group that had experienced the uncontrollable footshocks generally failed to escape at all – they seemed helpless. The degree and duration of this interference is related to the number, duration, and spacing of the trauma experience(s) and can last up to months (Seligman and Groves 1970), and the individual aversive events that make up the trauma cannot be too short (e.g., not less than 1–2 sec) no matter how numerous if one is to produce the Learned Helplessness effect (Overmier and Seligman 1967).

Most are familiar with “Learned Helplessness” which has been cited or invoked in texts more than 3000 times since its introduction and more than 50 times in 2016 according to PsycINFO. Some whole journal issues have been devoted to it. So why has Learned Helplessness remained in the research spotlight? We offer four reasons.

First, the observed phenomenon in the initial experiments was quite dramatic. Induced “helpless” animals would in phase 2 passively endure a series of minute-long continuous intense footshocks instead of trying to escape. This led to many of follow-up experiments (see review by Overmier and Lolordo 1998) using a number of vertebrate species including humans, fish, mice, and rats and other non-rodent species such as birds and even insects in variety of induction and assessment environments with surprisingly consistent proactive interference results. That is, it was a pretty reliable general phenomenon. Second, “Learned Helplessness” consisted of a syndrome of effects from the first three reported in the initial report of behavioral deficit, a cognitive/learning deficit, and an emotional deficit

(anhedonia) to several other less discussed features of the syndrome such as depletions of CNS neurotransmitters (e.g., Anisman et al. 1980), immunosuppression (Laudenslager et al. 1983), enhanced susceptibility to cancer tumor growth (Sklar and Anisman 1979), pain analgesia (Drugan and Maier 1983), anorexia and hypersensitive taste finickiness (Dess et al. 1988), and gastric ulcer (Overmier and Murison 2000). Third, Learned Helplessness became an animal model for testing for antidepressant drugs (e.g., Katz and Sibel 1982). Fourth and most importantly, Seligman (1974) hypothesized that Learned Helplessness in animals closely paralleled reactive depression in humans and that the further study of Learned Helplessness in animals and humans would yield insights into the behavioral, cognitive, and physiological mechanisms of depression. Shortly thereafter, Seligman (1975), in a popular book, extended the application of the presumed cognitive construct underlying Learned Helplessness to a wide variety of other dysphoric psychological phenomena affecting children, adults, and the aged. As Learned Helplessness theory was applied to human dysfunctions, it needed to be enriched with reference to human cognitions and attributions that could be studied (Abramson et al. 1978), but in doing so, it eliminated any *direct* causal chain between specific experiences and the resultant state of Learned Helplessness (see Overmier 1988).

Several reviews of the parallels between Learned Helplessness syndrome and human depressive psychopathology appeared (e.g., Overmier and Hellhammer 1988), but another by Foa et al. (1992) focused on parallels between Learned Helplessness and post-traumatic stress disorder (PTSD) and argued that Learned Helplessness was better as a model of PTSD. Indeed, some parallels to PTSD do seem more appropriate. A result has been new papers exploring Learned Helplessness as an animal model of PTSD (e.g., Koba et al. 2001). Why didn't Seligman initially link it to PTSD? For starters, PTSD was not a recognized diagnostic entity at the time. Further, of course, PTSD has diagnostic features overlapping with depression. But we note that many of the diagnostic features for PTSD are simply not

accessible in animals (e.g., reexperiencing the trauma via flashbacks and reportable nightmares, impaired concentration).

Many of the important proactive effects of Learned Helplessness inducing trauma have been linked to the uncontrollability of the trauma elements. Indeed, as noted, this became part of the definitional nexus for Learned Helplessness. It was certainly what Overmier and Seligman hypothesized in their 1967 paper, and it was what Seligman and Maier tested in their paper.

Mineka and Kihlstrom (1978) argued that dimensions of uncontrollability and unpredictability of events were separate contributory features that induce experimental neuroses. In that line, Overmier and Wielkiewicz (1983) argued that unpredictability of traumatic events is also an important feature for Learned Helplessness induction and has separable – albeit less dramatic – effects from uncontrollability and more specifically that the uncontrollability as one dimension contributed to the behavioral deficit, while unpredictability as an independent dimension contributed to the cognitive/associative/learning deficit of the Learned Helplessness syndrome. Dess et al. (1983) did an interesting confirmatory experiment that showed different temporal loci of effects of unpredictability and uncontrollability on the stressfulness of trauma experiences, both immediate and future ones.

Concurrent with the basic behavioral studies on Learned Helplessness, there was a parallel line of neuroscience analyses of the brain mechanisms that might underlie Learned Helplessness. Already briefly mentioned above were efforts to find parallels between the behavior and CNS neurotransmitter states and efforts to link findings to psychopharmacological treatments. A promising line of research from the Maier-Watkins laboratory on the neural basis of Learned Helplessness focused much research on the pain perception and the involved neural pathways after experiencing uncontrollable shocks. Special attention was given to the resulting activation of the dorsal raphe nucleus, and this culminated in recent work on the moderating role of the medial prefrontal cortex on the dorsal raphe after experiencing escapable – but not inescapable – shocks

(Maier 2015). This new neuroscience work suggests that the *original theory* of Learned Helplessness was wrong in hypothesizing that when events are uncontrollable and unpredictable that organisms learn that their actions are useless and thus they become helpless. Rather, the neuroscience data as reviewed suggest that helplessness is the direct primary result of an activated dorsal raphe and that experiencing controllable and predictable events and learning to control and to predict them are encoded in the medial prefrontal area and suppress the dorsal raphe output. This neuroscience data is exactly congruent with an earlier behavioral hypothesis (Minor et al. 1991) challenging the original Learned Helplessness concept and recharacterizing the nature of the empirical syndrome.

Preventing and overcoming Learned Helplessness is a topic that flows naturally from discovery and elaboration of the syndrome because of its likely important implications for human dysfunction and psychopathology. An understanding of Learned Helplessness should lead investigators to potential new approaches to therapy, prevention, and resilience.

First in this line of investigation, Seligman and Maier (1967) provided evidence that interference of Learned Helplessness was preventable by pretraining the dogs to learn that shock termination was contingent upon responding. Second, Seligman et al. (1968) highlighted the critical role of “taking back control in the face of adversity” by having the dogs guided (forced) to make a few escape response to terminate shock in the test after being previously exposed to inescapable and uncontrollable traumatic shock. This “putting through therapy” was successful in overcoming the otherwise manifested Learned Helplessness. Third, “therapeutic” action of electroconvulsive shocks was demonstrated in dogs (Dorworth and Overmier 1977) exposed to Learned Helplessness. Fourth, using rats as subjects, cessation conditioning (i.e., signaling the end of inescapable shocks) in the induction phase prevented the development of the interference effect of Learned Helplessness (Minor et al. 1990). Fifth, long-term physical activity prevented one the debilitating neurochemical depletion effects of Learned

Helplessness in rats as measured by an attenuation of 5-HT neural activity in the DRN that is thought to play a key role in the expression of Learned Helplessness (Greenwood et al. 2003). Sixth, group housing of mice in an enriched environment wherein the rats had opportunities for play and were spontaneously more active also minimized the negative impact of induced Learned Helplessness in comparison to mice group-housed in an impoverished environment (Chourbaji et al. 2005); the presumed mechanism for this was by supposedly improving physiological moderators of stress such as corticosterone levels among myriad others. Seventh, young rats handled during a 3-week period exhibited fewer negative consequences of Learned Helplessness when tested in adulthood, although no specific mechanism was identified (Costela et al. 1995). This could well be of practical value in child-rearing, although the effects of early handling/maternal separation are complex. Eighth, the efficacy of different pharmacological treatments has been established in many studies and continues to be of great interest (e.g., Takamori et al. 2001). Some of these findings likely have practical value, and all have heuristic value for further researches on Learned Helplessness.

Of course, no line of research is without at least some potential shortcomings. Learned Helplessness has been widely employed as an animal model for understanding mechanisms of depression. However, it is noteworthy that sex differences in animal models of psychopathology may lead us to question the applicability to men and women. Notably, Dalla et al. (2008) suggested that Learned Helplessness involves sex-specific behavioral effects in rats. The authors observed that the female rats initially exposed to uncontrollable electrical shocks did not show impairment in learning to escape on a subsequent escape task in comparison to male rats that were markedly impaired and did not learn to escape on this novel task. On the other hand, other researchers have found that Learned Helplessness can be induced in both males and females, although estrous state modulates its severity (Jenkins et al. 2001). Although this question of sex differences has not been a major focus of interest so far, it

clearly calls for more replications and investigations before drawing any firm conclusions; we believe that it deserves some attention in the future to confirm that Learned Helplessness is a valid animal model of depression, PTSD, and dysphoria relevant for both men and women.

The case of Learned Helplessness is an intriguing one. It emerged from early animal basic science experiments seeking to test aspects of Mowrer's theory of avoidance learning and led to possible applications to humans and therapeutic treatments or immunizations that increase the resilience and coping by humans. It illustrates well how at the outset, one cannot know where basic researches will lead nor their likely future values. In the course of experiments on Learned Helplessness, the field discovered more about behavior, learning, stress, ulcers, pain mechanisms, steroids, opioids, neurotransmitters, and regional processing interactions in the brain and probably about depression, PTSD, and dysphoria. It is still an ongoing story to which new researchers will continue to contribute and more new discoveries will emerge.

## Learning

José E. Burgos

Centro de Estudios e Investigaciones en  
Comportamiento, University of Guadalajara,  
Guadalajara, Jalisco, Mexico

## Synonyms

Discovery; Enlightenment; Finding; Finding out;  
Instruction; Knowing; Mastering; Schooling;  
Searching; Studying; Training; Understanding

Let us begin humbly: It is very hard, perhaps even impossible, to define learning *strictly*, in a conclusive, perfectly clear and precise way that specifies *all* the necessary and sufficient conditions (constitutive properties or essential attributes) for something to truly or really *be* learning and pleases most psychologists. As Bolles (1979) put it:

The big question—What is the fundamental nature of the learning process?—is as unsettled today as it has ever been. There is, however, less concern today than there used to be about this ultimate question. One reason for this loss of concern may be a growing skepticism about whether the question can ever be answered. A second and perhaps more important reason is that, even though there is little agreement about the basic *processes* of learning, a good agreement has grown about the *procedures* that produce learning. The procedures are relatively clear and useful, whereas the processes remain uncertain and rather conjectural. (p. 137)

This “big question” remains unsettled today, as others have admitted. Catania (2013) put it thus: “From the start, we must face the fact that we won’t be able to define learning. There are no satisfactory definitions” (p. 2). Haselgrove (2016) expressed a similar sentiment: “... it turns out to be relatively difficult to pin down an entirely satisfactory definition of the phenomenon” (p. 1). Mazur (2017) was no less humble: “... even specialists have difficulty defining the term *learning* precisely” (p. 2).

I will be equally humble and not try to give a strict definition either, but seek something far less hubristic, but this does not mean any less concern

over the nature of learning, despite reasonable skepticism about ever settling it. I read Catania’s reassuring defiance in the above quotation, “we won’t let that stop us,” as an advice not to let such skepticism intimidate us into lessening our concern over the nature of learning. We can still *do our best* to understand it as much as possible, even if only in an ever-closer but never final asymptotic approach of sorts. Who knows? We could find valuable clues along the way. Besides, there have been advances since Bolles’ book, a few of which I will mention later, which might illuminate the search.

It is common to speak of “the definition of learning,” but all proposals in this regard are too rough, preliminary, and tentative to deserve the name of “definitions,” as this term traditionally connotes all-too-lofty ideals of definiteness, clarity, and precision. At best, they are *working ideas* or *notions* of learning, as I will call them here. As such, it is wiser to take them all as open-ended and revisable.

In sum, instead of giving a definition of learning as such, I will engage in a standard philosophical and scientific task known as *historical-conceptual analysis*, but it will just be the very beginning of only a possible analysis. Many others are possible. Mine will be very far from being exhaustive, conclusive, perfectly clear and precise, or even simple. It will only take a few steps into one possible path or, rather, multiple thorny, convoluted paths crisscrossing in myriad dimensions. This entry, then, will only continue the search of the nature of learning, leaving it unfinished. If I could add a subtitle, the full title of this entry would be “Learning: Continuing the Search for Its Nature.” The search is likely endless, but, as is often the case, what matters is the adventure itself, more than its ending. Let us thus press onward into what may well be a fool’s errand, but undaunted by this possibility, inspired by Captain Kirk’s reaction in this dialogue from the *Star Trek* movie *Generations*:

**Kirk:** I take it the odds are against us and the situation is grim.

**Picard:** You could say that.

**Kirk:** ... Sounds like fun!

I will first summarize ordinary-English meanings of the term **learning**, beginning with its etymology and then fading in into modern meanings, ordinary and more technical in psychology. The second section presents how I view the current situation in discussions about the learning notion in psychology. The last section is the bulk of the entry, where I discuss the family of learning notions I see as the dominant one in the psychology of learning, giving possible reasons why that is the case but ending with a preference for notions that are more encompassing.

### Ordinary-English Meanings

The term's etymology gives some clues about the nature of learning, even if too vaguely. According to Skeat (1910, p. 334), for instance, the word "learning" is a derivation of "learn," which appeared in Middle English (roughly between 1200 and 1460) as "lernen," from the Anglo-Saxon "leornian" (between about 400 and 1150) and the Old German "linōn" (between about 700 and 1100), both meaning "to learn." Its Teutonic type "leisan," or "to trace out," the principal part of which, "leis," occurs in Gothic with the meaning "I know" in the sense of "I have found out." The Online Etymology Dictionary ([https://www.etymonline.com/word/learn#etymonline\\_v\\_6626](https://www.etymonline.com/word/learn#etymonline_v_6626)) provides a similar account but adds "to hear of, ascertain" and "to get knowledge, be cultivated; study, read, think about." According to this dictionary, the noun "learning" appeared in ordinary English around the fourteenth century AD as "leornung," with the base sense "study, action of acquiring knowledge."

These origins remain in current meanings. The entry for **learning** in a current ordinary-English dictionary (<https://en.oxforddictionaries.com/definition/learning>) includes this meaning: "The acquisition of knowledge or skills through study, experience, or being taught. Knowledge acquired through study, experience, or being taught." This meaning remains current in educational psychology, where the focus is on human learning in the classroom or school, but it is not my focus in this entry. Another dictionary (<https://www.merriam->

[webster.com/dictionary/learning](https://www.webster.com/dictionary/learning)) gives similar meanings but includes a more modern one closer to my focus: "1: the act or experience of one that learns. 2: knowledge or skill acquired by instruction or study people of good education and considerable learning. 3: modification of a behavioral tendency by experience (such as exposure to conditioning)."

Meaning (2) repeats the educational psychology one. Meaning (3) is more modern and closer to my focus here, applicable to creatures other than humans. It also echoes a notion widely cited in the field: "... learning refers to a more or less permanent change in behavior which occurs as a result of practice" (Kimble 1961, p. 2). Colman (2015) submitted a similar notion: "Any lasting change in behaviour resulting from experience, especially conditioning" (p. 416); he also included the more traditional notion: "The act or process of acquiring knowledge or skill, or knowledge gained by study" (ibid.).

I do not mean to reject the traditional idea of learning as knowledge acquisition by education in humans, but it is not my area of expertise, as important as it is. I am more familiar with the more general notions discussed in the experimental psychology of learning, my focus in this entry. The mention of conditioning in the preceding notion refers to a family of learning phenomena widely studied in experimental psychology, under the name of "associative learning." It includes Pavlovian (after Pavlov 1928; also known "classical" or "respondent") conditioning and operant (or instrumental) conditioning.

The other family, nonassociative learning, includes habituation and sensitization. These terms have their own entries in this encyclopedia, so I shall not discuss them at length, to avoid excessive overlap. I will focus on Pavlovian conditioning as a paradigmatic example of learning, only to make some general points about the nature of learning. I do not intend this focus to reduce all learning to Pavlovian conditioning, or even associative learning. I would like what follows to be applicable to as many phenomena as possible that have been called "learning," but I will not be able to fulfill this wish completely in this entry (perhaps in my lifetime). A proper assessment of

this generality will require extensive further discussion well beyond this entry.

## Two Families of Learning Notions in Psychology

Perhaps the most general disagreement among learning scientists over the nature of learning processes is whether it is behavioral or nonbehavioral (Burgos 2018). This disagreement has led to two seemingly irreconcilable families of notions of learning. According to behavioral notions, some kind of behavior or performance change (functionally related to certain external environmental conditions) is *constitutive* of, essential or fundamental to (at least *necessary* for something to *be*), learning (I shall use all those expressions equivalently). An example is Kimble's (1961) classical notion cited above. As usually cited, it seems to be purely behavioral in that it appears to view learning *only* as a kind of performance change functionally related to certain kind of external environmental conditions (but see below).

A behavioral notion need not be *purely* behavioral. Some are *impurely* behavioral by including nonbehavioral entities as *equally* constitutive of learning. For example, Corsini (1999) submitted this notion: "**learning** the process of acquiring new and relatively enduring information, behavior patterns, or abilities; modification of behavior as a result of practice, study, or experience" (p. 541). This notion is behavioral in that it includes a certain kind of behavior change as constitutive of learning, but impurely so, as it also postulates certain nonbehavioral features (information acquisition; more on this later) as equally constitutive of learning.

The other family consists of *purely* nonbehavioral notions, according to which no behavior change is essential to learning. They thus view learning *only* as an inferred, supposedly internal, process, *if* expressed in behavior. They thus view the term **learning** as *theoretical*, in the traditional sense of referring to publicly unobservable processes. The emphasized "if" means that learning can (in fact, quite often does) occur without any change in the *relevant* behavior or performance of

*interest*, the *behavior measured for the dependent variable*. Consequently, *this* performance is inessential to learning. (I mean all these emphases to anticipate a key clarification: the behavior to which these notions refer is not necessarily *any* behavior.)

Kimble's (1961) notion seems to be purely behavioral, but to conclude this would be hasty. Quotations of this notion, as abundant as they are, fail to mention that he referred to it as "factual" in viewing learning as "observable events in the physical world" (p. 2). Such notions, he clarified, "make no effort to describe underlying mechanisms or to identify the 'true nature' of learning" (p. 8). Kimble also referred to notions of learning that "attempt to accomplish such objectives" (p. 9) as "theoretical." He thus appears to have viewed the true nature of learning as given by underlying mechanisms, not behavior change.

## Purely Nonbehavioral Notions

Most psychologists find purely behavioral notions inadequate and prefer purely nonbehavioral notions. For example, Bolles (1976) submitted this notion: "... learning may be defined as the process of associating ordered events. Note that there is no evidence of learning at the time learning occurs; evidence of learning consists of a subsequent change in behavior" (p. 21). This notion echoes *associationism* (but see later), the most widely held view about the nature of learning. He elaborated as follows:

If an experimental situation provides an ordering of events such that one event follows another in a lawful manner, and if an animal's behavior changes as a result of this arbitrary ordering, then we may say learning has occurred. The learning itself is difficult to identify because it is not an observable thing or relationship but a hypothetical process, which has been variously conceived as forming a neural connection, building a habit, establishing an association, or acquiring an expectancy. But however the process is conceived, the change in behavior merely constitutes evidence of learning (ibid.).

Domjan (2015) proposed this notion: "Learning is an enduring change in the mechanisms of behavior involving specific stimuli and/or responses that results from prior experience with those of

similar stimuli and responses” (p. 13). He clarified that “... the preceding definition attributes learning to a change in the *mechanisms of behavior*, not to a change in behavior directly ... Learning is defined in terms of a change in the mechanisms of behavior to emphasize the distinction between learning and performance” (p. 13).

In making the learning-performance distinction, a common practice among most learning scientists, Domjan implies that learning is *not* behavior change. The purely nonbehavioral character of this notion seems clear: Behavior change is not constitutive, only evidence of learning. It is key not to confuse the two. *How* we know whether learning has occurred (evidence of learning) hinges on *what* is learning (the nature of learning). In order to know whether learning has occurred, we must *first* have *some* idea, however rough, of what is learning.

Olson and Hergenhahn (2016) provided a similar notion in a chapter entitled “What is learning?.” After paying lip service to a modified version of Kimble’s (1961) factual notion, they settled for the following:

... whatever we study in psychology, must be expressed through overt or covert behavior, but this does not mean that the behavior we study *is* learning. We study behavior so that we can make *inferences* concerning the process believed to be the cause of the behavioral changes we observe. In this case, that process is learning. Most learning theorists discussed in this book agree that the learning process cannot be studied directly; instead, its nature can only be inferred from changes in behavior ... most learning psychologists look on learning as a process that mediates behavior. For them, learning occurs as the result of certain experiences and precedes changes in behavior. In such a definition, learning is given the status of an **intervening variable** ... a theoretical process that is assumed to take place between the observed stimuli and responses ... Independent variables cause a change in the intervening variable (learning), which in turn causes a change in the dependent variable (behavior). (pp. 2–3)

## Why Prefer Purely Nonbehavioral Notions?

One answer to this question is the lack of compelling reasons against nonbehavioral notions. The

usual Skinnerian attacks of dualism, public unobservability, and impracticality leave such notions unscathed (Burgos and Killeen 2019). These attacks also apply to impurely behavioral notions. The attacks, then, seek to leave purely behavioral notions as the last ones standing.

Another answer has to do with the so-called “behavioural silence” argument (I will keep using the American form “behavioral”), formulated by Dickinson (1980) as follows:

... we cannot assume that nothing is learned in the absence of a behavioral change. ... the main reason for rejecting simple behaviourism was that learning could occur in the absence of any overt change in behaviour, or in other words that learning could be behaviourally silent. (p. 15)

This argument favors purely nonbehavioral notions of learning, but not just in theory. It also has some empirical support in laboratory observations of certain conditioning phenomena. Dickinson (1980) summarized one, but there are more. The support is indirect, but this does not make it any less convincing. The Skinnerian ideal (e.g., Skinner 1950) of definite (direct, hard, abundant) empirical support is too strict (Burgos and Killeen 2019).

A key clarification here (anticipated in Note 2), not explicit in defenses of the argument and purely nonbehavioral notions, is that “behavioral silence” here does not necessarily mean that animals are behaviorless throughout the training phase. I seriously doubt supporters of the argument believe this. Instead, following the principle of charitable interpretation (which I strive to do, with moderation), I interpret the argument (and the purely nonbehavioral notions it supports) as referring only to the behavior measured for the dependent variable.

**Conditioned suppression of barpressing in rats.** Rats are first trained to press a bar through operant contingencies (response-dependent reinforcement) and then receive pairings of a cue (the conditioned stimulus or CS, e.g., a light or a tone) with an electric shock applied to the paws (the unconditioned stimulus or US), in Pavlovian fashion. Afterwards, rats receive trials of the cue, which significantly reduce barpressing frequency.

Only studies of this phenomenon where the bar is *absent* during the Pavlovian training support the

behavioral-silence argument. In many, perhaps most studies, the bar remains present during this training, and some (e.g., Testa 1975) report a change in the behavior of interest (barpressing). These studies do not allow exclusion of the necessity of such change. However, the Pavlovian training in other studies (e.g., Ayres, Axelrod, Mercker, Muchnick, & Vigorito, 1985, Experiment 3) has occurred offline, without the bar. In these studies, no barpressing can occur during the training, which implies, according to purely behavioral notions, that no learning occurred. Yet, test trials of the cue with the bar reinstated result in a significant response suppression. This result implies, according to the behavioral-silence argument, that some learning occurred during the Pavlovian training phase, despite the non-occurrence of any change in the response.

**Pavlovian-instrumental transfer.** A related family of phenomena comprises Pavlovian-instrumental transfer (PIT), where Pavlovian conditioning facilitates operant conditioning. It is commonly studied with appetitive US and rewards. In specific PIT, the CS facilitates a response trained in operant conditioning with a reward used as the US initially paired with the CS. In general PIT, the CS facilitates a response trained in operant conditioning with a reward different from the US that was initially paired with the CS.

As in conditioned suppression, these phenomena provide a clearer support to the behavioral-silence argument if the operandum is absent during Pavlovian training, which is often the case in these studies. No change in the response of interest can occur without the operandum during Pavlovian training, which implies the absence of learning, according to behavioral notions. Despite this, as the behavioral-silence argument predicts and against behavioral notions, the facilitation of the operant response by the cue later on strongly suggests that some learning occurred during the Pavlovian training.

**Sensory preconditioning.** Subjects first receive trials of a target cue X (e.g., a light) paired (presented in some optimal temporal and probabilistic relation) with trials of another cue A (e.g., a tone). The US does not occur during this phase;

hence, nor does the UR, the response of interest. The kind of behavior change that according to behavioral notions constitutes Pavlovian conditioning (i.e., acquisition of the conditioned response or CR) cannot occur in this first phase.

Subjects then receive A-US pairings according to a standard Pavlovian procedure, followed by test trials of X alone. The result is a substantial CR to X (compared to a control group that did not receive the X-A pretraining), despite the fact that X was never paired with the US. According to the behavioral-silence argument, some learning must have occurred during the X-A pretraining, but whatever it is (many believe it is at least an X-A association), it does not require the occurrence of the unconditioned reflex of interest. This result is yet another challenge to behavioral notions.

**Latent inhibition (CS-preexposure effect).**

Subjects first receive a number of trials of a cue X without the US (cue preexposure), followed by X+ trials. Latent inhibition is a significant retardation in the acquisition of the CR during X+. Because the relevant change in the behavior of interest does not occur during the CS-preexposure phase, behavioral notions imply that no learning occurred during that phase. The results, once again, contradict this implication and support the behavioral-silence argument that some learning must have occurred during that phase, despite the absence of the relevant change in the behavior of interest.

It is common to distinguish between attentional and learning processes, even if the latter depend on the former. Most explanations of this phenomenon appeal only to *attentional* processes and, hence, postulate no associative learning during the CS-preexposure phase. This distinction, coupled with those explanations, would weaken the empirical support this phenomenon might lend to the behavioral-silence argument *if* this argument were restricted to associative learning, but there is no good reason to do this.

**US-preexposure effect.** In a related phenomenon, first reported by Randich (1981), subjects first receive preexposure to the US without any scheduled discrete cue as the CS, followed by Pavlovian CS-US training. Like latent inhibition, the effect is a significant retardation of the

acquisition of the CR, although the evidence is more complicated to explain. The dominant explanation of the associative effect is that the US is conditioned to the context during the pre-exposure phase, where the context is viewed as just another CS. Because the same context is present during the CS-US training, the context functions like a previously conditioned CS (A), which blocks conditioning to the new CS (X).

In short, according to this explanation, the effect is just another case of blocking a widely studied phenomenon in associative learning. Still, I do not view most other cases as evidence that supports the behavioral-silence argument. The reason is that such cases use the standard blocking procedure, which involves A as a *discrete* CS (in contrast to the continuous presence of contextual cues). Some of these cases also involve measuring responding to A during the A-US training, and this measuring shows a relevant behavior change. This change goes unreported in some studies that use the standard blocking procedure. Despite this, the explanation of the US-preexposure effect as a case of blocking assumes that such change occurs, rendering it largely unnecessary.

**Second-order conditioning in autoshaping.** Rescorla (1980, pp. 18–24) reported further evidence that empirically supports the behavioral-silence argument and crucially involves the phenomenon of autoshaping. This phenomenon is the acquisition of a skeletal, prototypical operant response (e.g., keypecking in pigeons) not unconditionally elicited by the primary reinforcer, at least not in the same way food unconditionally elicits salivation. This acquisition occurs under a Pavlovian cue-reinforcer contingency that operationally requires no responding, more reliably when the cue is visually localized where the animal is expected to respond (e.g., a light projected directly on a key, if the response of interest is the pigeons' keypecking).

In Rescorla's (1980, pp. 18–24) experiments, however, pigeons first received tone-food pairings. No keypecking occurred during this training, presumably because a tone is a diffuse cue that is not as precisely spatially localized as a key light. The implication of a purely behavioral

notion of learning as just some kind of performance change is that there was no learning during this phase, because there was no performance change *in the relevant response* (keypecking). However, in a second phase, the same pigeons received key light-tone pairings, according to a second-order conditioning procedure. Lo and behold, pigeons pecked the key at significant levels, compared to control pigeons that also received the light-tone but not the tone-food pairings. The implication is that the pigeons in the experimental condition must have learned something during the tone-food training, which seems more plausible than the implication from behavioral notions that the pigeons learned nothing during that training.

**Learning with impaired responding.** Other evidence that supports the behavioral-silence argument and, to this extent, purely nonbehavioral notions comes from reports of learning with impaired responses. The classical example is impairment of skeletal responses with curare. In the first report of this attempt, Harlow and Stagner (1933) reported that curarized cats and dogs failed *avoidance* conditioning of certain skeletal (striated muscle) responses (e.g., flexing a leg, leaping from a potentially painful place), but not pupil dilation (mydriasis), an autonomic response. The authors concluded that the "peripheral" or "motor view," akin to purely behavioral notions of learning, was correct.

This conclusion applied only to the skeletal responses the authors measured, insofar as they reported no impairment of the unconditioned mydriasis to an electric shock and successful Pavlovian conditioning of this response to a bell in the curarized dogs. This result would seem to support purely behavioral notions of learning with this response. However, Girden (1942) reported absence of a conditioned mydriasis response to a bell in dogs with elimination of sympathetic innervation to the right eye, although he did not report the effect of this elimination on the unconditioned mydriasis to the shock.

Not even Harlow and Stagner's (1933) limited conclusion held in the light of further evidence showing that other methods of skeletal response impairment (e.g., crushing spinal motor limb

innervations during training; e.g., Light and Gantt (1936) did not prevent a conditioned skeletal response after recovery from the impairment (regeneration of the innervations). Other evidence suggested that the impairing effects of curare were not restricted to muscle contraction, but also extend to the brain (more on this later). Harlow (1940) eventually retracted: "... the data from the curare experiments cannot be used to support the motor theory of learning" (p. 281).

**Conditioned inhibition.** Another phenomenon that could provide further empirical support of the behavioral-silence argument and, to this extent, purely nonbehavioral notions is conditioned inhibition, first reported by Pavlov (1928). In his early studies, he designed what is presently a standard procedure to obtain this phenomenon experimentally. The basic procedure (omitting all the necessary controls) consists in presenting compound AX- trials randomly intermixed with A+ trials, where A and X denote two different cues (e.g., a light and a tone) and "-" denotes the absence of the US and "+" a pairing with the US. The evidence shows that X becomes a conditioned inhibitor.

A major issue is that inhibition, contrary to excitation, lacks any overt behavioral expression, at least in the response system of interest, unconditionally elicited by the US. Therefore, no direct overt behavioral indicator allows for a reliable distinction between the absence of responding in conditioned inhibition and such absence in extinction or even to a *neutral* CS. The behavioral indicators of X as a conditioned inhibitor must then indirect. This issue led some to question the validity of the idea of inhibition in the psychology of learning.

For decades, there was little agreement on how solve this problem, until Rescorla's (1969) widely influential proposal: Determining whether X is a conditioned inhibitor requires an acquisition test and a summation test. X must "pass" *both* tests to consider it as a conditioned inhibitor. X passes an acquisition test if acquisition of the CR under X+ is significantly slower after a conditioned-inhibition procedure, compared to control groups that did not receive such training (or received different trainings). X passes the summation test

if responding to a BX compound is significantly lower in the experimental group, where B is yet another excitatory CS (sometimes called "transfer excitor").

Cole et al. (1997) reported the most compelling demonstration thus far of conditioned inhibition using both tests, but they admitted it might still be insufficient to warrant postulation of a construct of conditioned inhibition as a single fundamental learning process. To this extent, conditioned inhibition may be a weaker empirical support for the behavioral-silence argument than the other phenomena.

## In Sum

Overall, the preceding very brief account empirically favors purely nonbehavioral notions. Not only have the usual attacks against these notions failed. These notions also have some empirical support, even if indirect and limited to Pavlovian conditioning, although this limitation does not imply that all learning is Pavlovian conditioning. The thesis that some kind of behavior change is essential (at least necessary) to learning still lacks compelling empirical support, especially for operant conditioning, where any support is operationally impossible to obtain, even for purely nonbehavioral notions. This situation may change in the future. In the meantime, at the risk of being mistaken, I will follow the zeitgeist and dedicate the rest of this entry to a more detailed discussion of purely nonbehavioral notions.

## Subfamilies

The preceding discussion is not the end of the matter by any means. I have discussed purely nonbehavioral notions too sketchily. The behavioral-silence argument is valid and has some evidential support, but does not give an *unequivocal specific* answer to the key issue of what learning is. To put it more precisely, what do all learning processes have in common? What kind of process is learning? The features nonbehavioral notions postulate (nonbehavioral,

inferred from and mediating behavior, publicly unobservable) are too general. Many animal processes have such features but are not learning processes (e.g., protein synthesis, metabolism, renal filtration, oxygen transport by erythrocytes, phagocytosis by leukocytes, viral and bacterial infections, muscle fatigue, neurotransmitter synthesis, etc.), or so it would seem.

None of the evidence summarized above supports unequivocally a more precise account of what learning processes have in common that distinguishes from other kinds of processes. This situation is clear from the presence of numerous accounts in the literature, all of which are equally compatible with that evidence. I will dedicate this section to discuss some of them, in their two varieties: neurobiological and cognitive.

**Neurobiological notions.** Kimble (1961) believed that many psychologists of his time preferred these notions: “[m]any of the theoretical definitions of learning are physiological” (p. 9). Some quotations, however, use the more precise “neural.” Kimble (1961), for instance, quoted this assertion: “Learning is the process of the formation of relatively permanent neural circuits” (p. 9). This belief is not new by any means. Thorndike (1913) submitted the following notion: “Learning is connecting. . . There are millions” of connections, including “connections leading to actual conduction in neurones” (p. 54); “The process of learning is one of simple making and keeping connections and readinesses to conduct” (p. 56), hence the term **connectionism**, often used to label his position. Reminiscent of this connectionism is Hull’s (1943) notion in a section entitled “The Problem and General Nature of Learning”: “The essential nature of the learning process may . . . be stated quite simply. . . the process of learning consists in the strengthening of certain . . . connections as contrasted with others, or in the setting up of quite new connections” (pp. 68–69).

**Connections as synapses: the synaptacist notion.** Whether by “connections” Hull (1943) meant “synapses” is unclear, as he did not use the latter or its singular, despite having been coined decades earlier and his use of the term “neurones” a few times in his seminal book. The term **connection** is often used as equivalent to

“synapse,” but the two terms are not synonyms. The term **connection** is much broader and less technical, as it can refer to relations between myriad entities other than neurons (e.g., people, electrical circuits, murder cases, events, literary works, stimulus-response, etc.). The term **synapse** is more precise and technical, referring only to a connection between neurons. The expression **synaptic connection**, then, is not redundant. Nor does talk of “connection” necessarily refer to this expression, unless **connection** is used as synonymous with **synapse**, in which case, the latter is preferable.

Thorndike (1913) used “synapses” several times throughout his works, but only once in the book dedicated to the psychology of learning: “Ultimately degrees of strength of a connection in behavior will be defined as degrees of some anatomical or physiological fact whereby synapses between neurones differ in intimacy” (p. 3). This quotation, coupled with his above-cited notion of learning, suggests that he might have been the first to identify learning with *synaptic change*. (It is more customary in neuroscience to speak of “synaptic plasticity,” but I prefer to speak of synaptic change, as **plasticity** is a *dispositional* term that denotes a *propensity* to change, without necessarily any change actually taking place. The term **change**, in contrast, focuses on actual, not potential, learning as synaptic change.) although he used “connection” far more often and seemingly not always as synonymous with “synapse.” Such identification, if Thorndike indeed intended it, may well be the first expression of what could be called, for want to a better name, the *synaptacist* notion of learning, according to which learning is *just* synaptic change. More precisely, all learning processes are just synaptic-change processes.

This formulation is extreme, and no author has formulated it quite like this. Strictly, only assertions like “learning is essentially *only* synaptic change,” “*only* synaptic change is constitutive of learning,” or “learning is fundamentally *nothing more* than synaptic change” express the notion in such an extreme way. As far as I know, no author has put it exactly like this. Consequently, I will not attribute it to any particular author. However, I will keep discussing it as a clear, coherent, and precise conceptual possibility.

As formulated above, the notion would seem to suffice as a statement of the nature of learning. Unfortunately, it does not, because it is too superficial and general to be acceptable as a valid account of the nature of learning. To deserve such honor, the notion requires empirical support, the predominant way to evaluate and validate concepts in science. In the following sections, I summarize a few advances in that regard, leaving out most of the technical details.

As a brief reminder about the synapse concept today, most synapses studied in neuroscience are chemical and consist of a presynaptic process, a synaptic cleft, and a postsynaptic process. The presynaptic process is an axon terminal or button of a neuron, and the postsynaptic process can be a dendritic spine, shaft, soma, or even axon terminal of *another* neuron. The key feature of a synapse for the synapticist notion is its strength, neuroscientifically characterized in various ways. One is in terms of the degree of spatiotemporal coincidence between a presynaptic active zone and a postsynaptic density. The former varies directly with the amount of neuroactive substance (typically a neurotransmitter) released by the presynaptic process. The postsynaptic density is the proportion of receptors on a region of the postsynaptic process. In this characterization, stronger synapses are relatively stable, higher spatiotemporal coincidences between more highly active presynaptic zones and higher postsynaptic densities.

***Some evidence of synaptic changes during learning.*** There has been abundant research on this in behavioral neuroscience, but I cannot possibly do it justice in this short entry. I will only give one of the most representative examples: the groundbreaking, Nobel prize-winning research of Eric R. Kandel and colleagues with the marine snail *Aplysia californica*'s gill-withdrawal response. This response is unconditionally elicited by tactile stimulation to the animal's siphon, and its magnitude is given by its duration. This evidence has shown that all such forms of learning, at least in this species, involve relatively persistent, long-term changes in certain synapses.

In habituation, the decrease in the duration of the response by repeated stimulation of the siphon is highly correlated with a reduction in calcium influx to the axon terminals of the siphon sensory

neurons, which reduces ACh release. Sensitization, Pavlovian, and operant conditioning, in contrast, are highly correlated with serotonergic *facilitation* (via axo-axonic synapses) of ACh release, mediated by a second messenger (cAMP) that opens various ion channel species (calcium, potassium), induces the docking of synaptic vesicles to release sites, and even alters DNA in the nucleus.

A primary aim of this kind of research has been to make detailed measurements of behavioral, neuronal activation, and synaptic changes, to determine how they correlate across these levels of organization. Thus far, numerous studies suggest that such interlevel correlations are strong, although it is not immediately apparent exactly what this means for the synapticist notion of learning as just synaptic changes.

*What does it mean?* Such a strong correlation suggests a role of synaptic change in learning. Does it conclusively support a strict synapticist notion of learning as *only* synaptic change? Not quite, because changes in neuronal activations and behaviors still occur in those studies, and this precludes excluding them as possibly constitutive of learning. Takeuchi et al. (2014) have proposed that a convincing exclusion must meet four conditions, three of which involve experimental synaptic manipulations that raise enormous technical challenges. I will abbreviate them as the *DRAM* conditions, after the initial of the terms these authors used to name them (enclosed in double quotes in parentheses).

One (*D* for "detectability"), training in a learning task should bring about demonstrable changes in identified synapses of some brain region. Two (*R* for "retrograde alteration"), comparable modifications *after* training should alter performance during test. Three (*A* for "anterograde alteration"), experimental modifications of those synapses *before* training should alter performance during training. Four (*M* for "mimicry"), direct experimental production of comparable synaptic changes *without* any training should bring about performance comparable to that observed during test after training without such production. The absence of training in *M* implies the non-occurrence of neuronal activations and behaviors specifically caused by the training and, hence,

possibly constitutive of learning the task. Meeting these conditions is a matter of degree, not an all-or-none affair.

This very simplified outline does little justice to the formidable technical challenges this kind of research presents, but overall there has been great progress in approximating those conditions, although no single study has yet met them fully. Unsurprisingly, progress in approximating  $D$  has been greater with invertebrates, due to the relative simplicity of their nervous systems. *Aplysia californica*, discussed above, is the most widely known example. Knowledge of specific changes in identified synapses (e.g., from siphon and tail sensory neurons to gill motor neurons) critical for various forms of learning in this species has approximated  $D$  quite closely. The same can be said of other invertebrate species used in experimental learning research.

There has also been much progress in approximating the *DRAM* conditions in vertebrates, particularly rodents and birds, the most widely used animals in experimental learning research. Their nervous systems, however, are far more complex, which makes closer approximation to  $D$  and  $M$  that much more technically challenging. This research has approximated more closely  $A$ , mainly surgically, through certain brain lesions (e.g., the amygdala, which weakens various components of fear conditioning in rats).

Overall, the evidence lends reasonably good empirical support to the synapticist notion of learning. However, the support remains quite incomplete. The *DRAM* conditions remain to be tested with many other learning tasks, their underlying brain circuits, and species. Replicability of all these tests also needs to be assessed. Tests across different species, in particular, might encourage comparative research that could promote the kind of evolutionary thinking about learning that gives much importance to biological constraints on learning. All this research will be key to test the limits, generalities, specificities, and evolutionary relevance of the synapticist notion and, in this way, inform in detail about its validity as an account of the nature of learning. Because of all this, at present, it seems wiser to view the notion as a promising but still working hypothesis.

***The necessity to theorize.*** So far, I have spoken only about empirical support of the synapticistic notion and have hinted at the extraordinary growth of the experimental database on this, although more research is needed. Whether such undeniable empirical progress necessarily means a better *understanding* of the nature of learning is far less clear, as much hinges on exactly what understanding is. Empirical data are at least necessary for understanding. Some say it is sufficient, others disagree. I will side with the latter, following the venerable and widespread view in science that understanding requires *explanations* of observations, which in turn requires *theorizing*.

A major reason for theorizing is the *complexity* of the phenomena of interest. Theorizing, then, is simplification in the form of abstraction of a few elements or factors hypothesized to be essential to the phenomenon of interest. This divide-and-conquer strategy is common in all science, and neuroscience is not the exception. The search for the nature of learning, then, is at least as strongly theoretical as it is empirical, and the two ways feed on one another. The aims of theoretical work are explanatory and predictive, more easily achieved with simplified models. The more complex a model, the harder it will be to use it for these aims.

Such simplification is even more vital in relation to brains, which can be quite complex, even those of nonhuman species used in learning research, far simpler than human brains. This complexity is directly relevant to neurobiological notions of learning. A major lesson learning psychologists have learned (no pun intended) is that a brain need not be as complex as a human, or even a cat or dog, or even a rat or pigeon, or even an insect, brain to make the nature of learning very hard to discover. The complexity of such far simpler brains seems to be far more than enough for that.

There were early efforts, during the mid-twentieth century, to theorize about chemical transmission in single synapses and action potentials in single axons, through computational models that included only a few hypothesized essential features as quantitative factors. These models were foundational and set most of the tone of theoretical research in the following

decades, in what has come to be *computational neuroscience*. This research is a sort of very (perhaps too) strictly played imitation game that seeks to emulate as closely as possible specific features of neuronal and synaptic structure and functioning in specific circuits, as known from hard cellular and synaptic data. The effort is so strong that I cannot but wonder whether it has lost the main purpose of theorizing, which is, precisely, to simplify.

In any case, much of it has sought to improve, elaborate upon, and combine the early models, guided by the hypothesis that synaptic transmission in brain circuits depends crucially on neuronal activations (action potentials reaching axon terminals). Such combinations have been used to simulate the dynamics of various brain circuits functionally dependent on neuronal activations and synaptic transmission, as observed in vitro. In these simulations, synapses are often simulated as fixed, which is unrealistic for those who seek to play the imitation game (emulate brain structure and functioning) as strictly as possible. If computational-neuroscience models are to be applicable to learning in animals (more on this limitation later), theorizing about synaptic change is also needed.

*Enter Donald O. Hebb.* In the first effort to do this, Hebb (1949) continued the connectionist view initiated by Thorndike and Hull. For example, he proposed these notions:

Connections rigidly determine what animal or human being does, and their acquisition constitutes learning. (p. xvii)

Learning according to the present ideas consists of a lasting change of facilitations between the activities of specific neural structures. The change results when two structures (single pathways or assemblies) that have sufficient anatomical connections are active at the same time. (p. 180)

... one can conceive of conditioning as the establishment of relations between cerebral neurons (in the first place) and between systems of neurons (in the second). (ibid.)

Based on those notions, Hebb (1949) proposed his widely influential “neurophysiological principle”:

When an axon of cell A is near enough to excite a cell B and repeatedly or persistently takes part in firing it,

some growth process or metabolic change takes place in one or both cells such that A's efficiency, as one of the cells firing B, is increased. (p. 62).

This principle was the first hypothesis of synaptic change and remains quite influential today, especially in modeling, the kind of synaptic change believed to constitute hippocampal LTP. The evidence strongly suggests that this change follows the Hebbian principle, for which the latter has inspired models of the former, so much so that many view LTP as Hebbian in nature.

*Models of synaptic change in computational neuroscience.* Hebb's principle led to modeling synaptic change as a major research area in computational neuroscience. Most models of synaptic change come in two varieties, but both include some Hebbian component (refined to solve certain problems, e.g., prevent unlimited synaptic strengthening; to take into account long-term depression, a lasting synaptic weakening by extended low-frequency firing stimulation). Biophysical models, on the one hand, are more in line with most computational neuroscience modeling and seek to emulate the details of the biochemical and physiological processes thus far known to result in changes in synaptic transmission (a few of which I summarized above).

Phenomenological models, in contrast, treat synapses as *input-output black boxes*, leaving aside their molecular, physiological, or cellular details. Hence, these models are more abstract. Some view the pre- and postsynaptic firing rates as the key input, where higher (above-threshold) rates result in stronger, longer lasting excitatory synapses. Other phenomenological models view relative *timing* between pre- and postsynaptic pairs as the primary determinant of synaptic change (briefer times tend to promote more lasting synaptic strengthening).

*Neo-connectionist notions.* Still, his proposals anticipated many of the intuitions behind later theoretical developments. Far from fading, a connectionist view of learning reached critical momentum during the resurgence of connectionism in cognitive psychology and artificial intelligence during the mid-1980s. This new form of connectionism, for want of a better term, can be named “neo-connectionism,” to distinguish it

from the early forms of connectionism. After a period dominated by traditional, Turing-machine, symbolic artificial intelligence, neo-connectionism became strongly guided by the synaptocist notion of learning, where the use of neural network models has been the preferred mode of theorizing. Nowadays, learning in neural-network modeling is viewed as changes in the *connection weights* or “free parameters” of a neural network (see **neural network** in this encyclopedia). However, in contrast to computational neuroscience, computational modeling in neo-connectionism is far more abstract, as it seeks to play the imitation game much less strictly. New-connectionist models are not as closely guided by hard data about action potentials and synaptic plasticity as models in computational neuroscience. Consequently, the former tend to be much more abstract and simplified.

Here is an example of a neo-connectionist notion: “Setting the connection strengths correctly is what network learning is about” (Anderson, 1995, p. 55). In similar spirit and letter, Enquist and Ghirlanda (2005) assert that:

... a better definition of learning is “changes in memory caused by experience,” whether or not such changes are immediately reflected at the level of behavior. ... In neural network models, memory and learning can be given precise interpretations reflecting this definition. Memory is equal to connection weights, the analog of synapses in nervous systems. ... learning amounts to changes in the weights. (p. 130)

What makes the second definition better than the first? The authors give the behavioral-silence rationale mentioned above for nonbehavioral notions of learning: “An experience, however, may change later behavior without this being immediately apparent” (p. 130). In any case, these authors’ notion of learning seems to be very close to the synaptocist notion, albeit still far more abstract than its development in computational neuroscience. Connections in artificial neural networks are interpreted as very abstract synapses, whereas connection weights are interpreted as very abstract synaptic strengths.

The part of a connectionist neural network model that describes changes in connection weights is the learning rule. There are several

learning rules, usually separated into two families: supervised and unsupervised. In supervised learning, changes in the connection weights of a neural network are overseen by an imaginary teacher of sorts that tells the network when it has made a mistake in performing a certain task of interest. These networks only learn when they make mistakes: no mistakes, no learning. Literally, it is *just* learning by error. In unsupervised learning, networks learn on their own, without any teacher (for more details, see **neural networks** in this encyclopedia).

An early example of supervised learning in neural-network modeling is Rosenblatt’s (1958) perceptron, which the author presented in the title of his paper as “a probabilistic model for information storage and organization storage in the brain” (p. 386). The term “probabilistic” indicates that, contrary to most learning models in psychology, the perceptron is consistent with the general implication of early models of synaptic transmission at single synapses stochastic in nature. The term “information” in that title has wider ramifications that I will discuss later. But in current mathematical renditions of the model, the learning rule critically involves the computation of an error signal, defined as the arithmetic difference between the network’s actual output activation and a desired or expected output activation (dictated by the task of interest).

The Hebbian principle provided an early notion of unsupervised learning and has been mathematized in various ways in neural network modeling. All of them assume that the mathematical relation between the co-activations of connected neurons is *multiplicative*. The simplest version of this assumption is that the weight  $w$  of a connection between units  $i$  and  $j$  ( $w_{i,j}$ ) with activations  $a_i$  and  $a_j$  at time  $t$  equals the weight at  $t - 1$  (at the immediately preceding moment) plus the product of  $a_i$  and  $a_j$  at  $t$ . More succinctly:  $w_{i,j,t} = a_{i,t}a_{j,t}$ . This mathematical rendition of the Hebbian principle has been found inadequate for various reasons, but I need not get into further technical details here. Suffice it to say that connectionist notions like the ones illustrated here restrict learning to changes in synaptic strengths relevant to a certain task: Learning is nothing more than these

changes. The synapticist notion of learning thus seems to be held in connectionism.

Connectionist notions of learning flourished and became more mathematically oriented with the publication of the *Parallel Distributed Processing* (PDP) volumes (McClelland, Rumelhart, and The PDP Research Group 1986). However, the adoption of this approach in computational modeling of learning as studied experimentally in animals has been scarce. Most connectionist models have focused on Pavlovian conditioning and been inspired by the Rescorla and Wagner (1972) model. Perhaps, this situation is due to the preference most learning psychologists have for cognitive notions, which I will discuss later. Connectionist modeling of operant conditioning has been even less common, likely due to the Skinnerian view (e.g., Skinner 1950) that still dominates operant-conditioning research, which eschews any nonbehavioral theorizing as unnecessary, neurobiological theorizing included.

**Non-synapticist neurobiological notions.** Not all neurobiological notions restrict learning to synaptic change. In fact, an implication of synapticist notions seems like a conceptual stretch: If learning is *just* synaptic change, an *in vitro* neuronal circuit where only synaptic strengths change (e.g., in a strict test of the mimicry condition) can be said to learn. This implication does not obtain in neurobiological notions that are more inclusive by viewing other brain processes as equally constitutive of learning and, hence, get closer to impurely behavioral notions. An example is the beginning of the section entitled “What is learning?” of Dudai’s (1989) book:

It is generally accepted that learning is an experience-dependent modification in behaviour, or in potential to behave . . . . This definition may satisfy psychologists or ethologists, but possibly not neurobiologists. A neurobiological definition should take into account the level of analysis with which neurobiology is concerned, namely, neurones, neuronal circuits and nervous systems. . . . I suggest that learning be defined in terms of a fundamental property of nervous systems, which is their ability to encode internal representations.” (p. 100)

Dudai might be surprised to know that most psychologists of learning repudiate purely behavioral

notions, although they prefer cognitive notions, discussed in the next section. Another feature of this quotation, more directly relevant here, is the absence of the term **synapse**. Synapses are tacitly included in neuronal circuits and nervous systems.

By “internal representations” Dudai (1989) meant

“... structured bodies of information possessed by the organism about the world and about appropriate reactions to the world. Representations are, thus, neurally encoded stylized versions of the world, capable of guiding behaviour. Internal representations are expected to vary tremendously in their complexity. (ibid., p. 101)

Dudai might also be surprised to know that most cognitive notions of learning adopt the information processing/storage view, but without reference to any neurobiological processes. This absence implies that information processing/storage is not unique to nervous systems. Dudai also clarified that “Specific representations are encoded by the activity *and* connectivity of circuits” (ibid., p. 101, emphasis added) and that “Learning is a multilevel phenomenon, and its analysis can be performed at levels ranging from the molecular to the behavioral” (ibid., p. 102). In contrast to the synapticist notion, this neurobiological notion does not identify learning with synaptic change: Changes in neuronal *activation* processes and patterns constitute learning as well. Moreover, the notion includes the behavioral level, suggesting that the notion might be behavioral, after all, but impurely so.

Similarly, in his notion of learning as a “change in the mechanisms of behavior,” quoted above, Domjan (2015, p. 16, Figure 1.5) suggested nervous-system mechanisms as primary candidates for the nature of learning, viewing neural systems, circuits, cells, and synapses as “levels of analysis of learning.” This suggestion makes for a neurobiological notion that does not restrict the nature of learning to synaptic changes, but includes other brain processes. Domjan, though, in contrast to Dudai, clarifies that behavior is not constitutive, only indicative of learning. It is unclear whether Dudai believes the same.

Although the synapticist notion has good evidence in its favor, overall most of the research in the neuroscience of learning still seeks to determine correlations across different levels of organization (molecular, synaptic, cellular, and behavioral) in phenomena called “learning.” These correlations provide a key empirical basis for postulating causal relations between learning (nonbehaviorally viewed) and behavior (always keeping in mind that correlation is not causation). Consequently, the evidence in this research provides stronger support for neurobiological notions that are more inclusive than the synapticist notion.

**Cognitive notions.** Neurobiological notions are readily applicable to learning in animals that have nervous systems, even if so severely lesioned that might be said to be incomplete, as in spinal (decerebrated) vertebrates (e.g., Grau and Joynes 2005). (This research has prompted a debate that is yet another example of my claim in Notes 1 and 3 that conceptual discussions about learning are ontological in character. In this debate, Grau and Joynes (2005) expressed frustration at years of being questioned about whether they “were examining *true* learning,” where some reviewers gave “demerits for falling outside traditional categories” (p. 46). Such questioning is symptomatic of an ontological stance on the real nature of learning that certain behavioral changes in spinal vertebrates allegedly do not satisfy. Grau and Joynes (2005) put it thus: “Frustrated by this continued assault, we have turned the question around and asked why learning should be so narrowly defined?” (p. 46). Why, indeed. Presumably, they believe that a wider notion inclusive of spinal vertebrates could be a closer approximation to the real nature of learning.) These notions also apply to insects (e.g., Dukas 2018) and very simple invertebrates that do not seem to have much of a brain as we know it in vertebrates or even insects, but still have a nervous system.

The view, however, is inapplicable to learning in *aneural* organisms, which lack anything even close to a nervous system as traditionally conceived in neuroscience (system of interconnected *neurons*). Aneural organisms that have been attributed a learning ability are paramecia

(Armus et al. 2006), bacteria (e.g., Yi et al. 2000), and plants (e.g., Gagliano et al. 2016).

One way is to seek out a more inclusive notion that includes learning in neural and aneural organisms, perhaps even inorganic systems. Cognitive notions can fulfill this role, even if this might not be the main reason why most psychologists of learning prefer such notions. Their generality makes them applicable to any organism, even inorganic machines (see Burgos 2018), regardless of their physical constitution. Such generality can be quite alluring, reminiscent of the still elusive “theory of everything in physics.” Generality supposedly is one of highest if not *the* highest ideal of science. It can lead to major advances if pursued wisely, in particular, not at the cost of specificity.

**Learning as information processing.** Many if not most of these notions add the following idea: Whatever neurobiological processes constitute learning, they carry out *information processing*. This idea is present in some of the notions cited earlier, but there are many others. For example, Dukas (2018) proposed the following notion: “Learning is the acquisition and retention of neuronal representations of new information” (p. 257).

In these notions, information processing and storage are properties of brains. Therefore, information processing/storage is entirely compatible with brain processes. Unfortunately, others see a fundamental incompatibility. After his earlier associationist notion, Bolles (1979) proposed this one: “. . . learning consists *not* in the acquisition of S-R associations but in the assimilation and storage of information about the environment” (p. iii, emphasis added). Gallistel and King (2010) have also proposed such incompatibility, in what may be the most zealous view of learning as information processing with Turing-machine architecture, a combination known as “algorithmic information theory” or AIT.

Such extreme cognitive notions are against the more inclusive kind of notion I seek here. They preclude the possibility that instances of learning as a kind of brain process constitute a proper subset of learning processes as involving information processing/storage. Fortunately, these extreme notions are very debatable. Bolles

(1979) offers no rationale whatsoever for his above notion. Gallistel and King (2010) justify AIT by this claim: “the behavioral data *imply* that brains are powerful organs of computation” (p. viii, emphasis added). This claim is fallacious, if by “imply” they mean *deductive* or *formal* implication qua *logical entailment* from certain premises to a conclusion via the application of deductive inference rules (a reasonable interpretation, given their uncritical commitment to AIT). However, as logicians and philosophers of science clarified over a century ago, there is no rule to *deduce* theory from data, strictly speaking. The fact that certain behavioral data (e.g., dead reckoning) can be explained computationally does not mean they imply AIT.

Happily, most learning theorists, like the neuroscientists cited above, see information processing/storage as entirely compatible with certain brain processes. This compatibility is clear in most computational models of Pavlovian conditioning, which come in two varieties. In the cue-competition variety (e.g., Rescorla and Wagner 1972), different cues “compete” for a limited amount of association supported by the US. In the comparator variety (e.g., Stout and Miller 2007), associations change independently of one another, and their expression in performance depends on comparisons among them. An emphasis of how this expression obtains, known as a response rule, is a hallmark of these models. On this view, all Pavlovian conditioning phenomena differ primarily in how the expression of learning in performance occurs.

Both kinds of models, just like neurobiological notions, allow for talk of associations combined with talk of information processing/storage, without the fear of contradiction lurking in the more extreme notions discussed above. In those models, then, it is entirely valid to state, for example, that a CS reliably paired with the US is “more informative” of the occurrence of the US than a CS that is unreliably paired with the US. Such talk implies that learning as association formation relates closely to, perhaps is identical to, information processing, although not necessarily viewed as having Turing-machine architecture. It is also quite common in these models to speak of the CS

and US “representations,” although not necessarily viewed as symbolic in nature.

**Encompassing neurobiological notions.** Cognitive notions that allow for compatibility between associative processes and information processing/storage have been characteristically formulated without any reference to any brain processes. This feature makes these notions suitable for capturing learning in aneural organisms, perhaps even inorganic machines (see Burgos, 2018). Can they encompass learning according to neurobiological notions, as a kind of brain process? I think they can, based on viewing these cognitive notions as *abstractions* of neurobiological notions. It is crucial to this view that such notions allow for said compatibility, as associations are more easily interpreted as synapses and associative strengths as synaptic strengths. Less clear is how to interpret neuronal activations in these notions. One possibility is to view them as stimulus *representations* or attention to stimuli. This interpretation can accommodate the two kinds of brain processes postulated by neurobiological notions (changes in neuronal activations and synaptic strengths) into cognitive notions, at least in principle.

More precisely, these brain processes are *physical implementations or realizations* of the more abstract learning processes postulated in cognitive notions. The notion of a physical implementation is central to the widely influential functionalism about the mind (not to be confused with the Chicago psychological school). According to this philosophy, brain processes are just *one* physical implementation of mental (cognitive, perceptual) processes. Brain processes are not the only *possible* physical implementations of mental processes. The latter can *also* be implemented in other, non-neural kinds of physical systems, such as those found in aneural organisms and even inorganic machines. That is to say, the nature of mental processes, according to this philosophy, is not given by their physical implementation, but their functional features. Mental processes, then, can occur in physically very different systems.

Extending this philosophy to learning, cognitive notions could in principle encompass learning processes in aneural organisms as nonneural

physical realizations of the *same kinds* of processes postulated by these notions. If these processes are cognitive in nature, an implication is that aneural organisms have cognition, which seems like a conceptual stretch. Exactly how this counterintuitive implication could be handled remains an open issue. Still, this interpretation implies that learning processes could occur in physically very different systems, like humans as plants. It remains to be seen whether this interpretation leads to a more unified notion of learning. In particular, an issue is the extent to which the biological details of learning in aneural organisms satisfy the notion of information processing/storage.

## Learning to Learn

Roger K. Thomas  
Department of Psychology, University of  
Georgia, Athens, GA, USA

### Synonyms

Deutero-learning; Learning set formation;  
Transfer of learning

### Definition

Learning to learn refers to the observation that prior learning often facilitates subsequent learning.

### Introduction

... in the late 1940s he [Harlow] achieved a major conceptual and methodological breakthrough with his discovery of learning sets. (Suomi and LeRoy 1982, p. 321)

Harlow's 1949 article, clearly describing for the first time, the concept of learning set formation, is one of the most widely cited articles in the animal behavior literature. (Schrier and Thompson 1984, p. 109)

Harry F. Harlow (1905–1981) is known for discovering the learning set (e.g., learning how to learn) phenomenon .... (Rumbaugh 1997, p. 197)

Despite Harlow's students' (e.g., Schrier and Suomi) and colleagues' enthusiasm for attributing the "discovery" of "learning to learn" to Harlow, it had been known in various guises, such as "formal discipline" or "transfer of training," at least, since the 1890s (Hall 1966, pp. 477–479). Nevertheless, an important event in the study of learning to learn, especially with nonhuman animals, was the publication of Harry Harlow's concept of "learning set formation" and, more importantly, his developing methods to investigate it and providing insightful measures to assess it. This was first presented in his presidential address on May 7, 1948, at the meeting of the

Midwestern Psychological Association and then published in the *Psychological Review* (Harlow 1949).

Generally unrecognized, 7 years prior to Harlow (1949), Gregory Bateson (1942), using the term *deutero-learning*, published a highly similar conceptualization to Harlow's (1949) learning set formation. Originally, Bateson's was a 16-page commentary on a presentation by his wife, the renowned anthropologist, Margaret Mead. It was reprinted with the publisher's permission in Bateson's more accessible *Steps to an Ecology of Mind* (Bateson 1972a) where he added a significant, related essay (Bateson 1972b).

Although Bateson did not have empirical data as Harlow did, Bateson presented two hypothetical data graphs (Bateson 1972a; please consult Bateson for "Fig. 1" and "Fig. 2") that projected results that remarkably anticipated Harlow's (1949) first two experimental results graphs ("Fig. 2" and "Fig. 3"); Harlow's "Fig. 1" (please consult Harlow for "Figs. 1, 2, and 3") was the well-known Wisconsin General Testing Apparatus (WGTA) developed by Harlow at the University of Wisconsin. The WGTA's most important function was to prevent an experimenter from inadvertently giving animals cues to make correct responses. Additionally, both Bateson (1942) and Harlow (1949) used the phrase "learning to learn" referring to the processes each was writing about.

Perhaps for understandable reasons, Harlow did not cite Bateson's prior work, as it was in a relatively obscure source for animal learning investigators. However, priority per se is not an issue here, as neither Bateson nor Harlow claimed originality regarding "learning to learn." Because Bateson published his contribution first, it will be addressed first. However, Harlow's contribution had a greater impact on comparative cognition, and it will be addressed more extensively.

### Gregory Bateson (1904–1980) and Deutero-Learning

Bateson (1972a) coined the terms "proto-learning" and "deutero-learning" to make the following distinction.

Let us say that there are two sorts of gradient discernible in all continued learning. The gradient at any point on a simple learning curve (e.g., a curve of rote learning) we shall say chiefly represents rate of proto-learning. If, however, we inflict a series of *similar learning experiments* on the same subject, we shall find that in each successive experiment the subject has a somewhat steeper proto-learning gradient, that he learns somewhat more rapidly. This progressive change in rate of proto-learning, we will call deutero-learning. (p. 167)

Later, Bateson (1972b) renamed proto-learning and deutero-learning as Learning I and Learning II, and he anticipated an even higher order or learning, Learning III, which is mind-boggling in its implications. If someone can determine how to investigate it scientifically, it has the potential to have a far greater impact than deutero-learning or learning set formation. However, further consideration of that is not appropriate here, and this entry will continue using the term “deutero-learning.”

Bateson (1942) did not consider his concept of deutero-learning to be original. Before coining the terms proto-learning and deutero-learning, he had written:

Now it so happens that in the psychological laboratories there is a common phenomenon of a somewhat higher degree of abstraction or generality than those which the experiments are planned to elucidate. It is a commonplace that the experimental subject – whether animal or man, becomes a better subject after repeated experiments. He not only learns to salivate at the appropriate moments, or to recite the appropriate nonsense syllables; he also, in some way, *learns to learn*. He not only solves the problem set him by the experimenter, where each solving is a piece of simple learning; but, more than this, he becomes more and more skilled in the solving of problems. (Bateson 1972a, p. 166; emphasis added)

As Bateson expressed it, he had merely coined the term “deutero-learning,” “. . . to avoid the labor of defining operationally all the other terms in the field (transfer of learning, generalization etc.)” (Bateson 1972a, p. 167).

Among his predecessors Bateson cited Maier (1940). Bateson wrote “. . . the concept of deutero-learning can be seen as almost synonymous with Professor Maier’s concept of “direction” (Bateson 1972a, p. 167). Bateson was too generous.

Maier’s concept of “direction” differed from Bateson’s “deutero-learning” and Harlow’s “learning set formation,” because Maier referred vaguely to improvement over unrelated tasks and Maier did not show how “direction” might be quantified.

### Harry Harlow (1905–1981) “The Formation of Learning Sets”

As mentioned above, Harlow’s (1949) article was his presidential address at the meeting of the Midwestern Psychological Association in May, 1948. In terms of the chronological development of the learning set formation concept, a footnote to the 1949 article shows that it was based on research that was “. . . supported in part by grants from the Special Research Fund of the University of Wisconsin for 1944–1948” (Harlow 1949, p. 51). The origin of Harlow’s learning set formation may be traced to an article published in 1944 (Harlow 1944) whose manuscript was received on June 18, 1942. Thus, although Harlow did not use the phrase “learning set formation” until 1949, he may have been developing it empirically and contemporaneously with Bateson (1942). Meanwhile, it is the 1948 presidential address and the resulting 1949 article that are typically cited as the beginning of Harlow’s learning set formation, and they will be considered first.

In Harlow’s 1948 presidential address, he began to discuss the broader role that learning plays in human and nonhuman animals’ lives. He asserted that “Our emotional, personal, and intellectual characteristics are not the mere algebraic summation of a near infinity of stimulus-response bonds” (Harlow 1949, p. 51). He continued,

The learning of primary importance to primates, at least, is the formation of learning sets; it is the *learning how to learn efficiently* in the situations the animal frequently encounters. (p. 51)

Harlow then described some of his empirical research, including an illustration of the WGTA and several graphs of illustrative data. As noted earlier, Harlow’s empirically based Figs. 2 and

3 were remarkably well-predicted by Bateson's (1942/1972a) hypothetical data graphs, Figs. 1 and 2.

Perhaps because the article was the text for an oral presentation, Harlow cited no references. However, Suomi and Leroy (1982) listed Harlow's 323 publications in chronological order beginning in 1932 and ending in 1978. Near the end of Harlow's (1948) presidential address, he identified what he believed to be his unique contribution.

The emphasis throughout this paper has been on the role of the historical or experience variable in learning behavior- the forgotten variable in current learning theory and research. Hull's Neo-behaviorists have constantly emphasized the necessity for an historical approach in learning, yet they have not exploited it fully. Their experimental manipulation of the experience variable has been largely limited to the development of isolated habits and their generalization . . . . Psychologists working with human subjects have long believed in the phenomenon of learning sets and have even used sets as explanatory principles . . . . These psychologists have not, however, investigated the nature of these learning sets . . . we have carried out studies that outline the development and operation of specific learning sets . . . it is our hope that our limited data will be extended by those brave souls who study real men and real women. (pp. 64–65)

## The "Evolution" for Harlow of the Concept of Learning Set Formation

Harlow (1944) was his first experimental research article related to "learning set formation" (hereafter LSF). However, he did not use the phrase LSF; rather, he considered the interpretation that the discrimination learning was occurring *insightfully* based on the use of "hypotheses" (Harlow 1944, p. 7).

Later, in the Discussion section, Harlow described the LSF process, although, as already noted, he did not use the phrase "learning set formation."

Indeed, once a monkey has solved a preliminary series of discriminations and has formed habits of responding to stimulus objects regardless of their position in space, later discriminations will be solved in a single trial or less, in a majority of

cases. Thus, if the first response is by chance correct, no additional errors will be made. If the first response is by chance incorrect, the error will be corrected on the succeeding trial and no additional errors will be made. In gestalt terminology the discrimination learning is occurring 'insightfully'. (Harlow 1944, p. 10)

[Five paragraphs later]

. . . once appropriate *reaction sets* have been formed in monkeys these sets may be transferred from one pair of discrimination objects to another making it possible for the subjects to meet a strict criterion for formation of a discrimination with a minimum amount of specific training. (p. 11)

Zable's and Harlow's (1946) interpretational emphasis was on forming "hypotheses," but their use of "hypotheses" was not that developed later by Harlow's student, Marvin Levine, whose "win-stay, lose-shift" hypotheses became so well associated with LSF (Levine 1959). Levine meant, if the animal chooses correctly on trial 1, that is a "win" and to obtain maximum reinforcement on succeeding trials, it should "stay" with its original choice. If the animal chooses incorrectly in trial 1, that is to "lose" and it should "shift" to the other discriminandum to obtain maximum reinforcement. As tests of LSF developed, new problems might be introduced for varying numbers of trials. However, the common practice that eventually emerged was to introduce a new problem every six trials. Discriminanda have typically been objects, and Harlow often described the task as "object quality learning set."

Learning to learn can be investigated in other ways as Harlow (1959) did with reversal learning. Harlow's emphasis here was on the development of learning, and he used rhesus monkeys ranging from neonates to adults. One example was to use a Y maze to train an infant monkey to learn to first go to the left arm of the Y for reinforcement until it met a predetermined number of trials-to-criterion (e.g., 90% correct responses in 20 trials). Then, the investigator reverses location of the reinforcers to the right arm of the Y maze. Typically, there is a persistence in going to the left arm but eventually, the monkey learns that reinforcement is now received with responses to the right arm. After a number of reversals and if the animal is

learning to learn, it will detect the reversal more quickly. Often, one nonreinforced trial is sufficient to inform the animal that a reversal has occurred. Of course, reversal learning can be done in many ways. For example, rather than left versus right in a Y maze, the animal might learn reversals between, say, black versus white alleys with position of the alleys changed on 50% of the trials. Generally, Harlow's young monkeys also performed the alley reversal task well.

As noted, Harlow changed the left-right position of the "correct" alley in the black-white alley reversal task on 50% of the trials, and it is widely realized that with most tasks (including LSF), the positions of the discriminanda must be changed over trials randomly or quasi-randomly. Quasi-random changes have advantages as described by Fellows (1967) whose article includes quasi-random series that many investigators have used in their research.

The 6-trial, object quality LSF task has been used with many species, so it will be the remaining focus here. The experimenter determines which discriminandum will be reinforced (typically but not always with food) for the six trials. The animal can choose only by chance on trial 1, but if learns to learn, it will learn to use information about trial 1 to choose correctly (e.g., "win-stay, lose-shift") for the remaining five trials. Trial 2 performances have been the most used measure of LSF.

## A Failed Application of LSF

Warren (1965) suggested that LSF formation might be a good way to compare species' learning abilities, and he published a graph where the ordinate was PER CENT CORRECT ON TRIAL 2 and the abscissa was PROBLEMS. Warren reported data from six species. The best performer was a rhesus monkey with 85% correct on trial 2 after 400 problems. A rat and a squirrel tied for worst performance with 60% correct after 1800 problems.

This application of LSF reached its zenith with a graph presented by Hodos (1970) on which he plotted data from 16 species including two children. The best performer was a child (age

unspecified but  $IQ = 136$ ) who had 100% correct on Trial 2 after 100 problems. The tree shrew was the worst performer at 50% correct on trial 2 in 1000 problems.

However, Warren (1974), who had initiated the use of LSF as a way to compare learning abilities of various species, also brought it to its end when he wrote:

Primates differ from other mammals in their extraordinary development of the visual system. They surpass most other mammalian species in respect to their capacity for color vision, stereopsis, and visual acuity. . . it is apparent that we have no basis for guessing the degree to which the inferior performances of non-Primate species in visual learning set problems reflect an inferiority in visual sensitivity and perception instead of a defective capacity for learning. (Warren 1974), p. 448.

Warren and others (e.g., Thomas 1980) discussed other contextual variables that might provide some species with advantages and other species with disadvantages in performing learning tasks. Optimally, in species' learning or intelligence test comparisons, such contextual variables will be adapted to be most suitable for each species.

Warren (1974) cited a study by Slotnick and Katz (1974) who used olfactory learning set discriminanda (floral scents) to study LSF by rats. The scents could only be delivered one at a time via a complicated, expensive, and tedious-to-use apparatus. The authors did not report percentages correct on trial 2, but they did report a number errorless or one-error problems, and they "... suggested that a "win-stay, lose shift" hypothesis was in effect" (Slotnick and Katz 1974, p. 798).

Not cited by Warren (1974), Langworthy and Jennings (1972) used a much simpler and less expensive way to present olfactory discriminanda to study oddity concept learning by rats which can also reveal LSF as shown below. They used ping pong balls saturated with the odors of one of eight food flavorings. As a given odor might be odd on some problems and nonodd on other problems, no odor could be exclusively associated with either odd or nonodd.

Three balls, two of the same odors and the third of a different odor, were presented side by side on a platform holding an open-air chute in which the balls were inserted. Marks on the chute showed

how far the rat had to nudge the odd ball aside to access the food cup beneath it. Langworthy and Jennings (1972) reported good results, but it was unclear whether the food reinforcer was only beneath the odd ball. If so, it is possible that the rats detected the correct ball by smelling the food beneath it.

Thomas and Noble (1988) and Bailey and Thomas (1998) followed Langworthy and Jennings in using odoriferous ping pong balls as discriminanda, but among other differences, they used 16 (Thomas and Noble) or 18 (Bailey and Thomas) food flavorings and 5-trial problems. As with Langworthy and Jennings, no odor was associated exclusively with odd or nonodd. They also baited all food wells, so food odor could not be a cue to the odd ball.

Bailey and Thomas (1998) made other changes, and for present purposes their study might be considered the more useful than the other. Both studies were designed to determine whether rats might learn the oddity concept, but the problems were presented in a learning set paradigm. Neither Thomas and Noble (1988) nor Bailey and Thomas (1998) found evidence of oddity concept learning, as performances on the first trials of new problems were at chance, but Bailey and Thomas who administered 60 problems found that their three rats averaged 87% correct on trial 2, on problems 16–30 and 81% correct on trial 2 on problems 16–60.

## LSF's Place Among Other Learning Processes

Harlow (1958) identified some problems' association with the study of' the evolution of learning including:

Another difficulty lies in existing limitations to a precise classification of the forms of learning and learning problems into levels of difficulty... the problem is far from solved; and no one has even attempted to scale the various learning problems or classes of problems . . . (p. 269).

Before we can return to the topic of this section, it is necessary first to show the progress made since Harlow's observation just quoted.

Gagné (e.g., 1970), who focused on human learning, proposed a hierarchy of eight types of learning, which he asserted to encompass any and all types of human learning. They were, generally deemed to be hierarchical on the assumption that lower levels, usually, were prerequisites for higher levels. From lowest to highest in Gagné's hierarchy were signal learning (i.e., classical or Pavlovian conditioning), stimulus-response learning (i.e., operant conditioning), chaining, verbal association, discrimination learning, concept learning, rule learning, and problem solving. Gagné's examples for verbal association and for his top three levels were taken from human learning literature, and most would not be feasible with non-human animals.

Thomas (1980) sought to develop a comprehensive hierarchy of learning types that could be used with all animals including humans. Thomas discovered that Bourne's (1970) approach to concept learning, which was to base it on tasks constructed to comply with formal logic (explained below), could replace Gagné's highest three levels and still account fully for any and all types of learning at Gagné's three highest levels. Additionally, this approach could be used with humans and nonhuman animals.

Gagné (1970) regarded verbal association to be parallel to chaining, so verbal association being less amenable to testing among most animals could be eliminated from Thomas's hierarchy (Thomas 1980). Thomas noted that Gagné had overlooked a lower form of learning than signal learning, namely, habituation and its complementary process, sensitization. Gagné clearly described discrimination learning as learning multiple discrimination problems concurrently, so Thomas renamed it concurrent discrimination learning.

Bourne (1970) based concept learning on tasks that were constructed to comply with the truth-function tables in formal logic. Bourne's lowest level involved only the logical operations affirmation and negation, which Thomas considered to be the foundations for class concepts. For Thomas (1980), this became level 6, class concepts. Bourne's middle level of concepts were based on the logical operations, conjunction, disjunction, or conditional and their complementary processes,

all of which Bourne considered to be parallel processes. Agreeing with Bourne that they were parallel processes and assuming that class concepts were prerequisites for concepts based on them, Thomas's level 7 became relational concepts involving conjunction, disjunction, or conditional operations and their complementary processes. Finally, Bourne regarded the logical operation for the biconditional and its complementary process to be above the three at his middle level, because the conditional is a prerequisite to the biconditional. In Thomas's hierarchy, level 8 became relational concepts based on the biconditional and its complementary process. Most research has focused on the primary as opposed to the complementary processes, so the complementary processes will be ignored here henceforth. However, one must always assume they can be present and tasks may be constructed based on them. Thomas equated learning ability with intelligence, and he considers his hierarchy to be a learning-intelligence hierarchy.

### Thomas's Learning-Intelligence Hierarchy

8. Relational Concepts based on the Biconditional
7. Relational Concepts based on the Conditional, Conjunctive, or Disjunctive
6. Absolute and Relative Class Concepts based on Affirmation and Negation
5. Concurrent Discrimination Learning
4. Chaining (Chains of S-R Learning Units)
3. Stimulus-Response (S-R) Learning or Operant Conditioning
2. Classical or Pavlovian Conditioning
1. Habituation and Sensitization

Note that both Gagné's (1972) and Thomas's (1980) hierarchies are on an *ordinal scale*. Thomas followed Gagné's order generally; however, Thomas considers that levels 2 and 3 (Classical and Operant Conditioning, respectively) might be parallel. Also, as it has been shown that representative species from all vertebrate classes (except amphibians appear not to have been tested) can succeed to some extent at level 5, Thomas believes that most mammalian and avian differentiations in learning abilities are

likely to be found among Levels 6–8, class and relational concepts.

To show class concept learning at level 6, one must use trial-unique discriminanda, or if the same discriminanda are presented more than one time, evidence for concept learning must be limited to the data from the first trials of presentations of new discriminanda. Otherwise, the animal might have learned the task by rote based on trial and error. *With absolute class concepts, it is not necessary to compare discriminanda.* For example, if the concept being investigated is "tree" and the animal is shown trial-unique examples of trees, and if the animal knows or has acquired the concept of "tree," it will respond directly to the discriminandum of a tree to show that it recognizes new exemplars as being trees. Some exemplars may be a fuzzy fit, and those may cause errors (e.g., shrubs vs. trees).

With relative class concepts *it is necessary to compare discriminanda to affirm which discriminandum represents the concept.* Perhaps the most studied relative class concept with animals has been the "oddity concept." Typically, the animal is shown trial-unique examples of three discriminanda, two of which are identical and the other is different or "odd"; and to recognize which one is odd it must compare the discriminanda.

Since Thomas's first publication of the learning-intelligence hierarchy 1980, he has had occasion to make minor emendations (e.g., Bailey et al. 2007). In Bailey et al., Thomas addressed a matter that had puzzled him for decades, namely, where in the hierarchy of learning types does LSF fit. He decided it best fit as a parallel process subsumed under concurrent discrimination learning. For Gagné, concurrent discrimination learning referred to multiple discrimination problems learned in parallel. LSF refers to multiple discrimination problems learned serially. Thomas (2012) explained further why LSF should not be considered to be an instance of concept learning.

### Concluding Remarks

"Learning to learn" has a long history under a variety of labels. However, it was Gregory

Bateson and Harry Harlow who gave it a more substantial theoretical foundation, and Harlow provided clear means to investigate and measure it. Ironically, Bateson (1942, 1972a) had expressed doubt that it could ever be studied in the laboratory, although later (Bateson 1972b) acknowledged Harlow (1949).

Thomas (2012), who concluded that LSF is not at the level of concept learning, also wrote:

Nevertheless, some may consider it to be an open question whether to agree with Thomas and colleagues, and many who study concept learning in animals regarding (a) what “conceptualization” means or (b) that the necessary evidence for conceptualization requires that the subject respond correctly to trial-unique [exemplars] or first trials with new exemplars of the concept. For example, one might argue that learning a strategy or “rule” such as that which humans might verbalize as “win-stay, lose-shift” involves conceptualization. However, it must also be recognized that with animals it is unlikely that they learn anything akin to such verbalizations of a rule or strategy, not to overlook that it is unlikely that an experimenter could provide unequivocal evidence that they did. (p. 1968.

Finally, there may be room to advance the status of LSF, and that may be a challenge for future investigators.
